[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

Current climate models reproduce the seasonal cycle of Arctic sea ice extent with a multi-model mean error of less than about 10% for any given month. There is *robust evidence* that the downward trend in Arctic summer sea ice extent is better simulated than at the time of the AR4, with about one quarter of the simulations showing a trend as strong as, or stronger, than in observations over the satellite era (since 1979). There is a tendency for models to slightly overestimate sea ice extent in the Arctic (by about 10%) in winter and spring. In the Antarctic, the multi-model mean seasonal cycle agrees well with observations, but inter-model spread is roughly double that for the Arctic. Most models simulate a small decreasing trend in Antarctic sea ice extent, albeit with large inter-model spread, in contrast to the small increasing trend in observations. {9.4.3, Figures 9.22, 9.24}

Models are able to reproduce many features of the observed global and Northern Hemispher (NH) mean temperature variance on interannual to centennial time scales (*high confidence*), and most models are now able to reproduce the observed peak in variability associated with the El Niño (2- to 7-year period) in the Tropical Pacific. The ability to assess variability from millennial simulations is new since the AR4 and allows quantitative evaluation of model estimates of low-frequency climate variability. This is important when using climate models to separate signal and noise in detection and attribution studies (Chapter 10). {9.5.3, Figures 9.33, 9.35}

Many important modes of climate variability and intraseasonal to seasonal phenomena are reproduced by models, with some improvements evident since the AR4. The statistics of the global monsoon, the North Atlantic Oscillation, the El Niño-Southern Oscillation (ENSO), the Indian Ocean Dipole and the Quasi-Biennial Oscillation are simulated well by several models, although this assessment is tempered by the limited scope of analysis published so far, or by limited observations. There are also modes of variability that are not simulated well. These include modes of Atlantic Ocean variability of relevance to near term projections in Chapter 11 and ENSO teleconnections outside the tropical Pacific, of relevance to Chapter 14. There is *high confidence* that the multi-model statistics of monsoon and ENSO have improved since the AR4. However, this improvement does not occur in all models, and process-based analysis shows that biases remain in the background state and in the strength of associated feedbacks. {9.5.3, Figures 9.32, 9.35, 9.36}

There has been substantial progress since the AR4 in the assessment of model simulations of extreme events. Based on assessment of a suite of indices, the inter-model range of simulated climate extremes is similar to the spread amongst observationally based estimates in most regions. In addition, changes in the frequency of extreme warm and cold days and nights over the second half of the 20th century are consistent between models and observations, with the ensemble global mean time series generally falling within the range of observational estimates. The majority of models underestimate the sensitivity of extreme precipitation to temperature variability or trends, especially in the tropics, which implies that models may underestimate the projected increase in extreme precipitation in the future. Some high-resolution atmospheric models have been shown to reproduce observed year-to-year variability of Atlantic hurricane counts when forced with observed sea surface temperatures, though so far only a few studies of this kind are available. {9.5.4, Figure 9.37}

An important development since the AR4 is the more widespread use of Earth System models, which include an interactive carbon cycle. In the majority of these models, the simulated global land and ocean carbon sinks over the latter part of the 20th century fall within the range of observational estimates. However, the regional patterns of carbon uptake and release are less well reproduced, especially for NH land where models systematically underestimate the sink implied by atmospheric inversion techniques The ability of models to simulate carbon fluxes is important because these models are used to estimate 'compatible emissions' (carbon dioxide emission pathways compatible with a particular climate change target; see Chapter 6). {9.4.5, Figure 9.27}

The majority of Earth System models now include an interactive representation of aerosols, and make use of a consistent specification of anthropogenic sulphur dioxide emissions. However, uncertainties in sulphur cycle processes and natural sources and sinks remain and so, for example, the simulated aerosol optical depth over oceans ranges from 0.08 to 0.22 with roughly equal numbers of models over- and under-estimating the satellite-estimated value of 0.12. {9.1.2, 9.4.6, Table 9.1, Figure 9.29}

Time-varying ozone is now included in the latest suite of models, either prescribed or calculated interactively. Although in some models there is only *medium agreement* with observed changes in total column ozone, the inclusion of time-varying stratospheric ozone constitutes a substantial improvement since the AR4 where half of the models prescribed a constant climatology. As a result, there is *robust evidence* that the representation of climate forcing by stratospheric ozone has improved since the AR4. {9.4.1, Figure 9.10}

Regional downscaling methods are used to provide climate information at the smaller scales needed for many climate impact studies, and there is *high confidence* that downscaling adds value both in regions with highly variable topography and for various small-scale phenomena. Regional models necessarily inherit biases from the global models used to provide boundary conditions. Furthermore, the ability to systematically evaluate regional climate models, and statistical downscaling schemes, is hampered because coordinated intercomparison studies are still emerging. However, several studies have demonstrated that added value arises from higher resolution of stationary features like topography and coastlines, and from improved representation of small-scale processes like convective precipitation. {9.6.4}

Earth system Models of Intermediate Complexity (EMICs) provide simulations of millennial time-scale climate change, and are used as tools to interpret and expand upon the results of more comprehensive models. Although they are limited in the scope and resolution of information provided, EMIC simulations of global mean surface temperature, ocean heat content and carbon cycle response over the 20th century are consistent with the historical records and with more comprehensive models, suggesting that they can be used to provide calibrated projections of long-term transient climate response

and stabilization, as well as large ensembles and alternative, policy-relevant, scenarios. {9.4.1, 9.4.2, 9.4.5, Figures 9.8, 9.17, 9.27}

The Coupled Model Intercomparison Project Phase 5 (CMIP5) model spread in equilibrium climate sensitivity ranges from 2.1°C to 4.7°C and is very similar to the assessment in the AR4. No correlation is found between biases in global mean surface temperature and equilibrium climate sensitivity, and so mean temperature biases do not obviously affect the modelled response to GHG forcing. There is *very high confidence* that the primary factor contributing to the spread in equilibrium climate sensitivity continues to be the cloud feedback. This applies to both the modern climate and the LGM. There is likewise *very high confidence* that, consistent with observations, models show a strong positive correlation between tropospheric temperature and water vapour on regional to global scales, implying a positive water vapour feedback in both models and observations. {9.4.1, 9.7.2, Figures 9.9, 9.42, 9.43}

Climate and Earth System models are based on physical principles, and they reproduce many important aspects of observed climate. Both aspects contribute to our confidence in the models' suitability for their application in detection and attribution studies (Chapter 10) and for quantitative future predictions and projections (Chapters 11 to 14). In general, there is no direct means of translating quantitative measures of past performance into confident statements about fidelity of future climate projections. However, there is increasing evidence that some aspects of observed variability or trends are well correlated with inter-model differences in model projections for quantities such as Arctic summertime sea ice trends, snow albedo feedback, and the carbon loss from tropical land. These relationships provide a way, in principle, to transform an observable quantity into a constraint on future projections, but the application of such constraints remains an area of emerging research. There has been substantial progress since the AR4 in the methodology to assess the reliability of a multi-model ensemble, and various approaches to improve the precision of multi-model projections are being explored. However, there is still no universal strategy for weighting the projections from different models based on their historical performance. {9.8.3, Figure 9.45}

9.1 Climate Models and Their Characteristics

9.1.1 Scope and Overview of this Chapter

Climate models are the primary tools available for investigating the response of the climate system to various forcings, for making climate predictions on seasonal to decadal time scales and for making projections of future climate over the coming century and beyond. It is crucial therefore to evaluate the performance of these models, both individually and collectively. The focus of this chapter is primarily on the models whose results will be used in the detection and attribution Chapter 10 and the chapters that present and assess projections (Chapters 11 to 14; Annex I), and so this is necessarily an incomplete evaluation. In particular, this chapter draws heavily on model results collected as part of the Coupled Model Intercomparison Projects (CMIP3 and CMIP5) (Meehl et al., 2007; Taylor et al., 2012b), as these constitute a set of coordinated and thus consistent and increasingly well-documented climate model experiments. Other intercomparison efforts, such as those dealing with Regional Climate Models (RCMs) and those dealing with Earth System Models of Intermediate Complexity (EMICs) are also used. It should be noted that the CMIP3 model archive has been extensively evaluated, and much of that evaluation has taken place subsequent to the AR4. By comparison, the CMIP5 models are only now being evaluated and so there is less published literature available. Where possible we show results from both CMIP3 and CMIP5 models so as to illustrate changes in model performance over time; however, where only CMIP3 results are available, they still constitute a useful evaluation of model performance in that for many quantities, the CMIP3 and CMIP5 model performances are broadly similar.

The direct approach to model evaluation is to compare model output with observations and analyze the resulting difference. This requires knowledge of the errors and uncertainties in the observations, which have been discussed in Chapters 2 through 6. Where possible, averages over the same time period in both models and observations are compared, although for many quantities the observational record is rather short, or only observationally based estimates of the climatological mean are available. In cases where observations are lacking, we resort to intercomparison of model results to provide at least some quantification of model uncertainty via inter-model spread.

After a more thorough discussion of the climate models and methods for evaluation in Sections 9.1 and 9.2, we describe climate model experiments in Section 9.3, evaluate recent and longer-term records as simulated by climate models in Section 9.4, variability and extremes in Section 9.5, and regional-scale climate simulation including downscaling in Section 9.6. We conclude with a discussion of model performance and climate sensitivity in Section 9.7, and the relation between model performance and the credibility of future climate projections in Section 9.8.

9.1.2 Overview of Model Types to Be Evaluated

The models used in climate research range from simple energy balance models to complex Earth System Models (ESMs) requiring state of the art high-performance computing. The choice of model depends directly on the scientific question being addressed (Held, 2005; Collins et al., 2006d). Applications include simulating palaeo or historical climate, sensitivity and process studies for attribution and physical understanding, predicting near-term climate variability and change on seasonal to decadal time scales, making projections of future climate change over the coming century or more and downscaling such projections to provide more detail at the regional and local scale. Computational cost is a factor in all of these, and so simplified models (with reduced complexity or spatial resolution) can be used when larger ensembles or longer integrations are required. Examples include exploration of parameter sensitivity or simulations of climate change on the millennial or longer time scale. Here, we provide a brief overview of the climate models evaluated in this chapter.

9.1.2.1 Atmosphere–Ocean General Circulation Models

Atmosphere–Ocean General Circulation Models (AOGCMs) were the 'standard' climate models assessed in the AR4. Their primary function is to understand the dynamics of the physical components of the climate system (atmosphere, ocean, land and sea ice), and for making projections based on future greenhouse gas (GHG) and aerosol forcing. These models continue to be extensively used, and in particular are run (sometimes at higher resolution) for seasonal to decadal climate prediction applications in which biogeochemical feedbacks are not critical (see Chapter 11). In addition, high-resolution or variable-resolution AOGCMs are often used in process studies or applications with a focus on a particular region. An overview of the AOGCMs assessed in this chapter can be found in Table 9.1 and the details in Table 9.A.1. For some specific applications, an atmospheric component of such a model is used on its own.

9.1.2.2 Earth System Models

ESMs are the current state-of-the-art models, and they expand on AOGCMs to include representation of various biogeochemical cycles such as those involved in the carbon cycle, the sulphur cycle, or ozone (Flato, 2011). These models provide the most comprehensive tools available for simulating past and future response of the climate system to external forcing, in which biogeochemical feedbacks play an important role. An overview of the ESMs assessed in this chapter can be found in Table 9.1 and details in Table 9.A.1.

9.1.2.3 Earth System Models of Intermediate Complexity

EMICs attempt to include relevant components of the Earth system, but often in an idealized manner or at lower resolution than the models described above. These models are applied to certain scientific questions such as understanding climate feedbacks on millennial time scales or exploring sensitivities in which long model integrations or large ensembles are required (Claussen et al., 2002; Petoukhov et al., 2005). This class of models often includes Earth system components not yet included in all ESMs (e.g., ice sheets). As computing power increases, this model class has continued to advance in terms of resolution and complexity. An overview of EMICs assessed in this chapter and in the AR5 WG1 is provided in Table 9.2 with additional details in Table 9.A.2.

Table 9.1 | Main features of the Atmosphere–Ocean General Circulation Models (AOGCMs) and Earth System Models (ESMs) participating in Coupled Model Intercomparison Project Phase 5 (CMIP5), and a comparison with Coupled Model Intercomparison Project Phase 3 (CMIP3), including components and resolution of the atmosphere and the ocean models. Detailed CMIP5 model description can be found in Table 9.A.1 (* refers to Table 9.A.1 for more details). Official CMIP model names are used. HT stands for High-Top atmosphere, which has a fully resolved stratosphere with a model top above the stratopause. AMIP stands for models with atmosphere and land surface only, using observed sea surface temperature and sea ice extent. A component is coloured when it includes at least a physically based prognostic equation and at least a two-way coupling with another component, allowing climate feedbacks. For aerosols, lighter shading means 'semi-interactive' and darker shading means 'fully interactive'. The resolution of the land surface usually follows that of the atmosphere, and the resolution of the sea ice follows that of the ocean. In moving from CMIP3 to CMIP5, note the increased complexity and resolution as well as the absence of artificial flux correction (FC) used in some CMIP3 models.

Significant advances in EMIC capabilities are inclusion of ice sheets (UVic 2.9, Weaver et al., 2001; CLIMBER-2.4, Petoukhov et al., 2000; LOVECLIM, Goosse et al., 2010) and ocean sediment models (DCESS, Shaffer et al., 2008; UVic 2.9, Weaver et al., 2001; Bern3D-LPJ, Ritz et al., 2011). These additional interactive components provide critical feedbacks involved in sea level rise estimates and carbon cycle response on millennial time scales (Zickfeld et al., 2013). Further, the flexibility and efficiency of EMICs allow calibration to specific climate change events to remove potential biases.

9.1.2.4 Regional Climate Models

RCMs are limited-area models with representations of climate processes comparable to those in the atmospheric and land surface components of AOGCMs, though typically run without interactive ocean and sea ice. RCMs are often used to dynamically 'downscale' global model simulations for some particular geographical region to provide more detailed information (Laprise, 2008; Rummukainen, 2010). By contrast, empirical and statistical downscaling methods constitute a range of techniques to provide similar regional or local detail.

9.1.3 Model Improvements

The climate models assessed in this report have seen a number of improvements since the AR4. Model development is a complex and iterative task: improved physical process descriptions are developed, new model components are introduced and the resolution of the models is improved. After assembly of all model components, model parameters are adjusted, or tuned, to provide a stable model climate. The overall approach to model development and tuning is summarized in Box 9.1.

9.1.3.1 Parameterizations

Parameterizations are included in all model components to represent processes that cannot be explicitly resolved; they are evaluated both in isolation and in the context of the full model. The purpose of this section is to highlight recent developments in the parameterizations employed in each model component. Some details for individual models are listed in Table 9.1.

9.1.3.1.1 Atmosphere

Atmospheric models must parameterize a wide range of processes, including those associated with atmospheric convection and clouds, cloud-microphysical and aerosol processes and their interaction, boundary layer processes, as well as radiation and the treatment of unresolved gravity waves. Advances made in the representation of cloud processes, including aerosol–cloud and cloud–radiation interactions, and atmospheric convection are described in Sections 7.2.3 and 7.4.

Improvements in representing the atmospheric boundary layer since the AR4 have focussed on basic boundary layer processes, the representation of the stable boundary layer, and boundary layer clouds (Teixeira et al., 2008). Several global models have successfully adopted new approaches to the parameterization of shallow cumulus convection and moist boundary layer turbulence that acknowledge their

Box 9.1 | Climate Model Development and Tuning

The Atmosphere–Ocean General Circulation Models, Earth System Models and Regional Climate Models evaluated here are based on fundamental laws of nature (e.g., energy, mass and momentum conservation). The development of climate models involves several principal steps:

1. Expressing the system's physical laws in mathematical terms. This requires theoretical and observational work in deriving and simplifying mathematical expressions that best describe the system.

2. Implementing these mathematical expressions on a computer. This requires developing numerical methods that allow the solution of the discretized mathematical expressions, usually implemented on some form of grid such as the latitude–longitude–height grid for atmospheric or oceanic models.

3. Building and implementing conceptual models (usually referred to as parameterizations) for those processes that cannot be represented explicitly, either because of their complexity (e.g., biochemical processes in vegetation) or because the spatial and/or temporal scales on which they occur are not resolved by the discretized model equations (e.g., cloud processes and turbulence). The development of parameterizations has become very complex (e.g., Jakob, 2010) and is often achieved by developing conceptual models of the process of interest in isolation using observations and comprehensive process models. The complexity of each process representation is constrained by observations, computational resources and current knowledge (e.g., Randall et al., 2007).

The application of state-of-the-art climate models requires significant supercomputing resources. Limitations in those resources lead to additional constraints. Even when using the most powerful computers, compromises need to be made in three main areas:

1. Numerical implementations allow for a choice of grid spacing and time step, usually referred to as 'model resolution'. Higher model resolution generally leads to mathematically more accurate models (although not necessarily more reliable simulations) but also to higher computational costs. The finite resolution of climate models implies that the effects of certain processes must be represented through parameterizations (e.g., the carbon cycle or cloud and precipitation processes; see Chapters 6 and 7).

2. The climate system contains many processes, the relative importance of which varies with the time scale of interest (e.g., the carbon cycle). Hence compromises to include or exclude certain processes or components in a model must be made, recognizing that an increase in complexity generally leads to an increase in computational cost (Hurrell et al., 2009).

3. Owing to uncertainties in the model formulation and the initial state, any individual simulation represents only one of the possible pathways the climate system might follow. To allow some evaluation of these uncertainties, it is necessary to carry out a number of simulations either with several models or by using an ensemble of simulations with a single model, both of which increase computational cost.

Trade-offs amongst the various considerations outlined above are guided by the intended model application and lead to the several classes of models introduced in Section 9.1.2.

Individual model components (e.g., the atmosphere, the ocean, etc.) are typically first evaluated in isolation as part of the model development process. For instance, the atmospheric component can be evaluated by prescribing sea surface temperature (SST) (Gates et al., 1999) or the ocean and land components by prescribing atmospheric conditions (Barnier et al., 2006; Griffies et al., 2009). Subsequently, the various components are assembled into a comprehensive model, which then undergoes a systematic evaluation. At this stage, a small subset of model parameters remains to be adjusted so that the model adheres to large-scale observational constraints (often global averages). This final parameter adjustment procedure is usually referred to as 'model tuning'. Model tuning aims to match observed climate system behaviour and so is connected to judgements as to what constitutes a skilful representation of the Earth's climate. For instance, maintaining the global mean top of the atmosphere (TOA) energy balance in a simulation of pre-industrial climate is essential to prevent the climate system from drifting to an unrealistic state. The models used in this report almost universally contain adjustments to parameters in their treatment of clouds to fulfil this important constraint of the climate system (Watanabe et al., 2010; Donner et al., 2011; Gent et al., 2011; Golaz et al., 2011; Martin et al., 2011; Hazeleger et al., 2012; Mauritsen et al., 2012; Hourdin et al., 2013).

With very few exceptions (Mauritsen et al., 2012; Hourdin et al., 2013) modelling centres do not routinely describe in detail how they tune their models. Therefore the complete list of observational constraints toward which a particular model is tuned is generally not

(continued on next page)

Box 9.1 (continued)

available. However, it is clear that tuning involves trade-offs; this keeps the number of constraints that can be used small and usually focuses on global mean measures related to budgets of energy, mass and momentum. It has been shown for at least one model that the tuning process does not necessarily lead to a single, unique set of parameters for a given model, but that different combinations of parameters can yield equally plausible models (Mauritsen et al., 2012). Hence the need for model tuning may increase model uncertainty. There have been recent efforts to develop systematic parameter optimization methods, but owing to model complexity they cannot yet be applied to fully coupled climate models (Neelin et al., 2010).

Model tuning directly influences the evaluation of climate models, as the quantities that are tuned cannot be used in model evaluation. Quantities closely related to those tuned will provide only weak tests of model performance. Nonetheless, by focusing on those quantities not generally involved in model tuning while discounting metrics clearly related to it, it is possible to gain insight into model performance. Model quality is tested most rigorously through the concurrent use of many model quantities, evaluation techniques, and performance metrics that together cover a wide range of emergent (or un-tuned) model behaviour.

The requirement for model tuning raises the question of whether climate models are reliable for future climate projections. Models are not tuned to match a particular future; they are tuned to reproduce a small subset of global mean observationally based constraints. What emerges is that the models that plausibly reproduce the past, universally display significant warming under increasing greenhouse gas concentrations, consistent with our physical understanding.

close mutual coupling. One new development is the Eddy-Diffusivity-Mass-Flux (EDMF) approach (Siebesma et al., 2007; Rio and Hourdin, 2008; Neggers, 2009; Neggers et al., 2009; Rio et al., 2010). The EDMF approach, like the shallow cumulus scheme of Park and Bretherton (2009), determines the cumulus-base mass flux from the statistical distribution of boundary layer updraft properties, a conceptual advance over the *ad hoc* closure assumptions used in the past. Realistic treatment of the stable boundary layer remains difficult (Beare et al., 2006; Cuxart et al., 2006; Svensson and Holtslag, 2009) with implications for modelling of the diurnal cycle of temperature even under clear skies (Svensson et al., 2011).

Parameterizations of unresolved orographic and non-orographic gravity-wave drag (GWD) have seen only a few changes since the AR4 (e.g., Richter et al., 2010; Geller et al., 2011). In addition to new formulations, the estimation of the parameters used in the GWD schemes has recently been advanced through the availability of satellite and ground-based observations of gravity-wave momentum fluxes, high-resolution numerical modelling, and focussed process studies (Alexander et al., 2010). Evidence from the Numerical Weather Prediction community that important terrain-generated features of the atmospheric circulation are better represented at higher model resolution has recently been confirmed (Watanabe et al., 2008; Jung et al., 2012).

9.1.3.1.2 Ocean

Ocean components in contemporary climate models generally have horizontal resolutions that are too coarse to admit mesoscale eddies. Consequently, such models typically employ some version of the Redi (Redi, 1982) neutral diffusion and Gent and McWilliams (Gent and McWilliams, 1990) eddy advection parameterization (see also Gent et al., 1995; McDougall and McIntosh, 2001). Since the AR4, a focus has been on how parameterized mesoscale eddy fluxes in the ocean interior interact with boundary layer turbulence (Gnanadesikan et al., 2007; Danabasoglu et al., 2008; Ferrari et al., 2008, 2010). Another focus concerns eddy diffusivity, with many CMIP5 models employing flow-dependent schemes. Both of these refinements are important for the mean state and the response to changing forcing, especially in the Southern Ocean (Hallberg and Gnanadesikan, 2006; Boning et al., 2008; Farneti et al., 2010; Farneti and Gent, 2011; Gent and Danabasoglu, 2011; Hofmann and Morales Maqueda, 2011).

In addition to mesoscale eddies, there has been a growing awareness of the role that sub-mesoscale eddies and fronts play in restratifying the mixed layer (Boccaletti et al., 2007; Fox-Kemper et al., 2008; Klein and Lapeyre, 2009), and the parameterization of Fox-Kemper et al. (2011) is now used in some CMIP5 models.

There is an active research effort on the representation of dianeutral mixing associated with breaking gravity waves (MacKinnon et al., 2009), with this work adding rigour to the prototype energetically consistent abyssal tidal mixing parameterization of Simmons et al. (2004) now used in several climate models (e.g., Jayne, 2009; Danabasoglu et al., 2012). The transport of dense water down-slope by gravity currents (e.g., Legg et al., 2008, 2009) has also been the subject of focussed efforts, with associated parameterizations making their way into some CMIP5 models (Jackson et al., 2008b; Legg et al., 2009; Danabasoglu et al., 2010).

9.1.3.1.3 Land

Land surface properties such as vegetation, soil type and the amount of water stored on the land as soil moisture, snow and groundwater all strongly influence climate, particularly through their effects on surface albedo and evapotranspiration. These climatic effects can be profound; for example, it has been suggested that changes in the state of the land surface may have played an important part in the severity and length of the 2003 European drought (Fischer et al., 2007), and

that more than 60% of the projected increase in interannual summer temperature variability in Europe is due to soil moisture–temperature feedbacks (Seneviratne et al., 2006).

Land surface schemes calculate the fluxes of heat, water and momentum between the land and the atmosphere. At the time of the AR4, even the more advanced land surface schemes suffered from obvious simplifications, such as the need to prescribe rather than simulate the vegetation cover and a tendency to ignore lateral flows of water and sub-gridscale heterogeneity in soil moisture (Pitman, 2003). Since the AR4, a number of climate models have included some representation of vegetation dynamics (see Sections 9.1.3.2.5 and 9.4.4.3), land–atmosphere CO_2 exchange (see Section 9.4.5), sub-gridscale hydrology (Oleson et al., 2008b) and changes in land use (see Section 9.4.4.4).

9.1.3.1.4 Sea ice

Most large-scale sea ice processes, such as basic thermodynamics and dynamics, are well understood and well represented in models (Hunke et al., 2010). However, important details of sea ice dynamics and deformation are not captured, especially at small scales (Coon et al., 2007; Girard et al., 2009; Hutchings et al., 2011). Currently, sea ice model development is focussed mainly on (1) more precise descriptions of physical processes such as microstructure evolution and anisotropy and (2) including biological and chemical species. Many models now include some representation of sub-grid-scale thickness variations, along with a description of mechanical redistribution that converts thinner ice to thicker ice under deformation (Hunke et al., 2010).

Sea ice albedo has long been recognized as a critical aspect of the global heat balance. The average ice surface albedo on the scale of a climate model grid cell is (as on land) the result of a mixture of surface types: bare ice, melting ice, snow-covered ice, open water, etc. Many sea ice models use a relatively simple albedo parameterization that specifies four albedo values: cold snow; warm, melting snow; cold, bare ice; and warm, melting ice, and the specific values may be subject to tuning (e.g., Losch et al., 2010). Some parameterizations take into account the ice and snow thickness, spectral band and surface melt (e.g., Pedersen et al., 2009; Vancoppenolle et al., 2009). Solar radiation may be distributed within the ice column assuming exponential decay or via a more complex multiple-scattering radiative transfer scheme (Briegleb and Light, 2007).

Snow model development for sea ice has lagged behind terrestrial snow models. Lecomte et al. (2011) introduced vertically varying snow temperature, density and conductivity to improve vertical heat conduction and melting in a 1D model intended for climate simulation, but many physical processes affecting the evolution of the snow pack, such as redistribution by wind, moisture transport (including flooding and snow ice formation) and snow grain size evolution, still are not included in most climate models.

Salinity affects the thermodynamic properties of sea ice, and is used in the calculation of fresh water and salt exchanges at the ice–ocean interface (Hunke et al., 2011). Some models allow the salinity to vary in time (Schramm et al., 1997), while others assume a salinity profile that is constant (e.g., Bitz and Lipscomb, 1999). Another new thrust is the inclusion of chemistry and biogeochemistry (Piot and von Glasow, 2008; Zhao et al., 2008; Vancoppenolle et al., 2010; Hunke et al., 2011), with dependencies on the ice microstructure and salinity profile.

Melt ponds can drain through interconnected brine channels when the ice becomes warm and permeable. This flushing can effectively clean the ice of salt, nutrients, and other inclusions, which affect the albedo, conductivity and biogeochemical processes and thereby play a role in climate change. Advanced parameterizations for melt ponds are making their way into sea ice components of global climate models (e.g., Flocco et al., 2012; Hunke et al., 2013).

9.1.3.2 New Components and Couplings: Emergence of Earth System Modelling

9.1.3.2.1 Carbon cycle

The omission of internally consistent feedbacks among the physical, chemical and biogeochemical processes in the Earth's climate system is a limitation of AOGCMs. The conceptual issue is that the physical climate influences natural sources and sinks of CO_2 and methane (CH_4), the two most important long-lived GHGs. ESMs incorporate many of the important biogeochemical processes, making it possible to simulate the evolution of these radiatively active species based on their emissions from natural and anthropogenic sources together with their interactions with the rest of the Earth system. Alternatively, when forced with specified concentrations, a model can be used to diagnose these sources with feedbacks included (Hibbard et al., 2007). Given the large natural sources and sinks of CO_2 relative to anthropogenic emissions, and given the primacy of CO_2 among anthropogenic GHGs, some of the most important enhancements are the addition of terrestrial and oceanic carbon cycles. These cycles have been incorporated into many models (Christian et al., 2010; Tjiputra et al., 2010) used to make projections of climate change (Schurgers et al., 2008; Jungclaus et al., 2010). Several ESMs now include coupled carbon and nitrogen cycles (Thornton et al., 2007; Gerber et al., 2010; Zaehle and Dalmonech, 2011) in order to simulate the interactions of nitrogen compounds with ecosystem productivity, GHGs including nitrous oxide (N_2O) and ozone (O_3), and global carbon sequestration (Zaehle and Dalmonech, 2011).

Oceanic uptake of CO_2 is highly variable in space and time, and is determined by the interplay between the biogeochemical and physical processes in the ocean. About half of CMIP5 models make use of schemes that partition marine ecosystems into nutrients, plankton, zooplankton and detritus (hence called NPZD-type models) while others use a more simplified representation of ocean biogeochemistry (see Table 9.A.1). These NPZD-type models allow simulation of some of the important feedbacks between climate and oceanic CO_2 uptake, but are limited by the lack of marine ecosystem dynamics. Some efforts have been made to include more plankton groups or plankton functional types in the models (Le Quere et al., 2005) with as-yet uncertain implications for Earth system response.

Ocean acidification and the associated decrease in calcification in many marine organisms provides a negative feedback on atmospheric CO_2 increase (Ridgwell et al., 2007a). New-generation models therefore include various parameterizations of calcium carbonate ($CaCO_3$)

production as a function of the saturation state of seawater with respect to calcite (Gehlen et al., 2007; Ridgwell et al., 2007a; Ilyina et al., 2009) or partial pressure CO_2 (pCO_2; Heinze, 2004). On centennial to multi-millennial scales, deep-sea carbonate sediments neutralize atmospheric CO_2. Some CMIP5 models include the sediment carbon reservoir, and progress has been made toward refined sediment representation in the models (Heinze et al., 2009).

9.1.3.2.2 Aerosol particles

The treatment of aerosol particles has advanced since the AR4. Many AOGCMs and ESMs now include the basic features of the sulphur cycle and so represent both the direct effect of sulphate aerosol, along with some of the more complex indirect effects involving cloud droplet number and size. Further, several AOGCMs and ESMs are currently capable of simulating the mass, number, size distribution and mixing state of interacting multi-component aerosol particles (Bauer et al., 2008b; Liu et al., 2012b). The incorporation of more physically complete representations of aerosol often improves the simulated climate under historical and present-day conditions, including the mean pattern and interannual variability in continental rainfall (Rotstayn et al., 2010, 2011). However, despite the addition of aerosol–cloud interactions to many AOGCMs and ESMs since the AR4, the representation of aerosol particles and their interaction with clouds and radiative transfer remains an important source of uncertainty (see Sections 7.3.5 and 7.4). Additional aerosol-related topics that have received attention include the connection between dust aerosol and ocean biogeochemistry, the production of oceanic dimethylsulphide (DMS, a natural source of sulphate aerosol), and vegetation interactions with organic atmospheric chemistry (Collins et al., 2011).

9.1.3.2.3 Methane cycle and permafrost

In addition to CO_2, an increasing number of ESMs and EMICs are also incorporating components of the CH_4 cycle, for example, atmospheric CH_4 chemistry and wetland emissions, to quantify some of the feedbacks from changes in CH_4 sources and sinks under a warming climate (Stocker et al., 2012). Some models now simulate the evolution of the permafrost carbon stock (Khvorostyanov et al., 2008a, 2008b), and in some cases this is integrated with the representation of terrestrial and oceanic CH_4 cycles (Volodin, 2008b; Volodin et al., 2010).

9.1.3.2.4 Dynamic global vegetation models and wildland fires

One of the potentially more significant effects of climate change is the alteration of the distribution, speciation and life cycle of vegetated ecosystems (Bergengren et al., 2001, 2011). Vegetation has a significant influence on the surface energy balance, exchanges of non-CO_2 GHGs and the terrestrial carbon sink. Systematic shifts in vegetation, for example, northward migration of boreal forests, would therefore impose biogeophysical feedbacks on the physical climate system (Clark et al., 2011). In order to include these effects in projections of climate change, several dynamic global vegetation models (DGVMs) have been developed and deployed in ESMs (Cramer et al., 2001; Sitch et al., 2008; Ostle et al., 2009). Although agriculture and managed forests are not yet generally incorporated, DGVMs can simulate the interactions among natural and anthropogenic drivers of global warming, the state of terrestrial ecosystems and ecological feedbacks on further climate change. The incorporation of DGVMs has required considerable improvement in the physics of coupled models to produce stable and realistic distributions of flora (Oleson et al., 2008b). The improvements include better treatments of surface, subsurface and soil hydrological processes; the exchange of water with the atmosphere; and the discharge of water into rivers and streams. Whereas the first DGVMs have been coupled primarily to the carbon cycle, the current generation of DGVMs are being extended to include ecological sources and sinks of other non-CO_2 trace gases including CH_4, N_2O, biogenic volatile organic compounds (BVOCs) and nitrogen oxides collectively known as NO_x (Arneth et al., 2010). BVOCs and NO_x can alter the lifetime of some GHGs and act as precursors for secondary organic aerosols (SOAs) and ozone. Disturbance of the natural landscape by fire has significant climatic effects through its impact on vegetation and through its emissions of GHGs, aerosols and aerosol precursors. Because the frequency of wildland fires increases rapidly with increases in ambient temperature (Westerling et al., 2006), the effects of fires are projected to grow over the 21st century (Kloster et al., 2012). The interactions of fires with the rest of the climate system are now being introduced into ESMs (Arora and Boer, 2005; Pechony and Shindell, 2009; Shevliakova et al., 2009).

9.1.3.2.5 Land use/land cover change

The impacts of land use and land cover change on the environment and climate are explicitly included as part of the Representative Concentration Pathways (RCPs; cf. Chapters 1 and 12) used for climate projections to be assessed in later chapters (Moss et al., 2010). Several important types of land use and land cover change include effects of agriculture and changing agricultural practices, including the potential for widespread introduction of biofuel crops; the management of forests for preservation, wood harvest and production of woody biofuel stock; and the global trends toward greater urbanization. ESMs include increasingly detailed treatments of crops and their interaction with the landscape (Arora and Boer, 2010; Smith et al., 2010a, 2010b), forest management (Bellassen et al., 2010, 2011) and the interactions between urban areas and the surrounding climate systems (Oleson et al., 2008a).

9.1.3.2.6 Chemistry–climate interactions and stratosphere–troposphere coupling

Important chemistry–climate interactions such as the impact of the ozone hole and recovery on Southern Hemisphere (SH) climate or the radiative effects of stratospheric water vapour changes on surface temperature have been confirmed in multiple studies (SPARC-CCMVal, 2010; WMO, 2011). In the majority of the CMIP5 simulations stratospheric ozone is prescribed. The main advance since the AR4 is that time-varying rather than constant stratospheric ozone is now generally used. In addition, several CMIP5 models treat stratospheric chemistry interactively, thus prognostically calculating stratospheric ozone and other chemical constituents. Important chemistry–climate interactions such as an increased influx of stratospheric ozone in a warmer climate that results in higher ozone burdens in the troposphere have also been identified (Young et al., 2013). Ten of the CMIP5 models simulate tropospheric chemistry interactively whereas it is prescribed in the remaining models (see Table 9.1 and Eyring et al. (2013)).

It is now widely accepted that in addition to the influence of tropospheric circulation and climate change on the stratosphere, stratospheric dynamics can in turn influence the tropospheric circulation and its variability (SPARC-CCMVal, 2010; WMO, 2011). As a result, many climate models now have the ability to include a fully resolved stratosphere with a model top above the stratopause, located at around 50 km. The subset of CMIP5 models with high-top configurations is compared to the set of low-top models with a model top below the stratopause in several studies (Charlton-Perez et al., 2012; Hardiman et al., 2012; Wilcox et al., 2012), although other factors such as differences in tropospheric warming or ozone could affect the two sub-ensembles.

9.1.3.2.7 Land ice sheets

The rate of melt water release from the Greenland and Antarctic ice sheets in response to climate change remains a major source of uncertainty in projections of sea level rise (see Sections 13.4.3 and 13.4.4). Until recently, the long-term response of these ice sheets to alterations in the surrounding atmosphere and ocean has been simulated using offline models. Several ESMs currently have the capability to have ice sheet component models coupled to the rest of the climate system (Driesschaert et al., 2007; Charbit et al., 2008; Vizcaino et al., 2008; Huybrechts et al., 2011; Robinson et al., 2012) although these capabilities are not exercised for CMIP5.

9.1.3.2.8 Additional features in ocean–atmosphere coupling

Several features in the coupling between the ocean and the atmosphere have become more widespread since the AR4. The bulk formulae used to compute the turbulent fluxes of heat, water and momentum at the air–sea interface, have been revised. A number of models now consider the ocean surface current when calculating wind stress (e.g., Luo et al., 2005; Jungclaus et al., 2006). The coupling frequency has been increased in some cases to include the diurnal cycle, which was shown to reduce the SST bias in the tropical Pacific (Schmidt et al., 2006; Bernie et al., 2008; Ham et al., 2010). Several models now represent the coupling between the penetration of the solar radiation into the ocean and light-absorbing chlorophyll, with some implications on the representation of the mean climate and climate variability (Murtugudde et al., 2002; Wetzel et al., 2006). This coupling is achieved either by prescribing the chlorophyll distribution from observations, or by computing the chlorophyll distribution with an ocean biogeochemical model (e.g., Arora et al., 2009).

9.1.3.3 Resolution

The typical horizontal resolution (defined here as horizontal grid spacing) for current AOGCMs and ESMs is roughly 1 to 2 degrees for the atmospheric component and around 1 degree for the ocean (Table 9.1). The typical number of vertical layers is around 30 to 40 for the atmosphere and around 30 to 60 for the ocean (note that some 'high-top' models may have 80 or more vertical levels in the atmosphere). There has been some modest increase in model resolution since the AR4, especially for the near-term simulations (e.g., around 0.5 degree for the atmosphere in some cases), based on increased availability of more powerful computers. For the models used in long-term simulations with interactive biogeochemistry, the resolution has not increased substantially due to the trade-off against higher complexity in such models. Since the AR4, typical regional climate model resolution has increased from around 50 km to around 25 km (see Section 9.6.2.2), and the impact of this has been explored with multi-decadal regional simulations (e.g., Christensen et al., 2010). In some cases, RCMs are being run at 10 km resolution or higher (e.g., Kanada et al., 2008; Kusaka et al., 2010; van Roosmalen et al., 2010; Kendon et al., 2012).

Higher resolution can sometimes lead to a stepwise, rather than incremental, improvement in model performance (e.g., Roberts et al., 2004; Shaffrey et al., 2009). For example, ocean models undergo a transition from laminar to eddy-permitting when the computational grid contains more than one or two grid points per first baroclinic Rossby radius (i.e., finer than 50 km at low latitudes and 10 km at high latitudes) (Smith et al., 2000; McWilliams, 2008). Such mesoscale eddy-permitting ocean models better capture the large amount of energy contained in fronts, boundary currents, and time dependent eddy features (e.g., McClean et al., 2006). Models run at such resolution have been used for some climate simulations, though much work remains before they are as mature as the coarser models currently in use (Bryan et al., 2007; Bryan et al., 2010; Farneti et al., 2010; McClean et al., 2011; Delworth et al., 2012).

Similarly, atmospheric models with grids that allow the explicit representation of convective cloud systems (i.e., finer than a few kilometres) avoid employing a parameterization of their effects—a long-standing source of uncertainty in climate models. For example, Kendon et al. (2012) simulated the climate of the UK region over a 20-year period at 1.5 km resolution, and demonstrated several improvements of errors typical of coarser resolution models. Further discussion of this is provided in Section 7.2.2.

9.2 Techniques for Assessing Model Performance

Systematic evaluation of models through comparisons with observations is a prerequisite to applying them confidently. Several significant developments in model evaluation have occurred since the AR4 and are assessed in this section. This is followed by a description of the overall approach to evaluation taken in this chapter and a discussion of its known limitations.

9.2.1 New Developments in Model Evaluation Approaches

9.2.1.1 Evaluating the Overall Model Results

The most straightforward approach to evaluate models is to compare simulated quantities (e.g., global distributions of temperature, precipitation, radiation etc.) with corresponding observationally based estimates (e.g., Gleckler et al., 2008; Pincus et al., 2008; Reichler and Kim, 2008). A significant development since the AR4 is the increased use of quantitative statistical measures, referred to as performance metrics. The use of such metrics simplifies synthesis and visualization of model performance (Gleckler et al., 2008; Pincus et al., 2008; Waugh and Eyring, 2008; Cadule et al., 2010; Sahany et al., 2012) and enables the

quantitative assessment of model improvements over time (Reichler and Kim, 2008). Recent work has addressed redundancy of multiple performance metrics through methods such as cluster analysis (Yokoi et al., 2011; Nishii et al., 2012).

9.2.1.2 Isolating Processes

To understand the cause of model errors it is necessary to evaluate the representation of processes both in the context of the full model and in isolation. A number of evaluation techniques to achieve both process and component isolation have been developed. One involves the so-called 'regime-oriented' approach to process evaluation. Instead of averaging model results in time (e.g., seasonal averages) or space (e.g., global averages), results are averaged within categories that describe physically distinct regimes of the system. Applications of this approach since the AR4 include the use of circulation regimes (Bellucci et al., 2010; Brown et al., 2010b; Brient and Bony, 2012; Ichikawa et al., 2012), cloud regimes (Williams and Brooks, 2008; Chen and Del Genio, 2009; Williams and Webb, 2009; Tsushima et al., 2013) and thermodynamic states (Sahany et al., 2012; Su, 2012). The application of new observations, such as vertically resolved cloud and water vapour information from satellites (Jiang et al., 2012a; Konsta et al., 2012; Quaas, 2012) and water isotopes (Risi et al., 2012a; Risi et al., 2012b), has also enhanced the ability to evaluate processes in climate models.

Another approach involves the isolation of model components or parameterizations in off-line simulations, such as Single Column Models of the atmosphere. Results of such simulations are compared to measurements from field studies or to results of more detailed process models (Randall et al., 2003). Numerous process evaluation data sets have been collected since the AR4 (Redelsperger et al., 2006; Illingworth et al., 2007; Verlinde et al., 2007; May et al., 2008; Wood et al., 2011) and have been applied to the evaluation of climate model processes (Xie et al., 2008; Boone et al., 2009; Boyle and Klein, 2010; Hourdin et al., 2010). These studies are crucial to test the realism of the process formulations that underpin climate models.

9.2.1.3 Instrument Simulators

Satellites provide nearly global coverage, sampling across many meteorological conditions. This makes them powerful tools for model evaluation. The conventional approach has been to convert satellite-observed radiation information to 'model-equivalents' (Stephens and Kummerow, 2007), and these have been used in numerous studies (Allan et al., 2007; Gleckler et al., 2008; Li et al., 2008; Pincus et al., 2008; Waliser et al., 2009b; Li et al., 2011a, 2012a; Jiang et al., 2012a). A challenge is that limitations of the satellite sensors demand various assumptions in order to convert a satellite measurement into a 'model equivalent' climate variable.

An alternative approach is to calculate 'observation-equivalents' from models using radiative transfer calculations to simulate what the satellite would provide if the satellite system were 'observing' the model. This approach is usually referred to as an 'instrument simulator'. Microphysical assumptions (which differ from model to model) can be included in the simulators, avoiding inconsistencies. A simulator for cloud properties from the International Cloud Satellite Climatology Project (ISCCP) (Yu et al., 1996; Klein and Jakob, 1999; Webb et al., 2001) has been widely used for model evaluation since the AR4 (Chen and Del Genio, 2009; Marchand et al., 2009; Wyant et al., 2009; Yokohata et al., 2010), often in conjunction with statistical techniques to separate model clouds into cloud regimes (e.g., Field et al., 2008; Williams and Brooks, 2008; Williams and Webb, 2009). New simulators for other satellite products have also been developed and are increasingly applied for model evaluation (Bodas-Salcedo et al., 2011). Although often focussed on clouds and precipitation, the simulator approach has also been used successfully for other variables such as upper tropospheric humidity (Allan et al., 2003; Iacono et al., 2003; Ringer et al., 2003; Brogniez et al., 2005; Brogniez and Pierrehumbert, 2007; Zhang et al., 2008b; Bodas-Salcedo et al., 2011). Although providing an alternative to the use of model-equivalents from observations, instrument simulators have limitations (Pincus et al., 2012) and are best applied in combination with other model evaluation techniques.

9.2.1.4 Initial Value Techniques

To be able to forecast the weather a few days ahead, knowledge of the present state of the atmosphere is of primary importance. In contrast, climate predictions and projections simulate the statistics of weather seasons to centuries in advance. Despite their differences, both weather predictions and projections of future climate are performed with very similar atmospheric model components. The atmospheric component of climate models can be integrated as a weather prediction model if initialized appropriately (Phillips et al., 2004). This allows testing parameterized sub-grid scale processes without the complication of feedbacks substantially altering the underlying state of the atmosphere.

The application of these techniques since the AR4 has led to some new insights. For example, many of the systematic errors in the modelled climate develop within a few days of simulation, highlighting the important role of fast, parameterized processes (Klein et al., 2006; Boyle et al., 2008; Xie et al., 2012). Errors in cloud properties for example were shown to be present within a few days in a forecast in at least some models (Williams and Brooks, 2008), although this was not the case in another model (Boyle and Klein, 2010; Zhang et al., 2010b). Other studies have highlighted the advantage of such methodologies for the detailed evaluation of model processes using observations that are available only for limited locations and times (Williamson and Olson, 2007; Bodas-Salcedo et al., 2008; Xie et al., 2008; Hannay et al., 2009; Boyle and Klein, 2010), an approach that is difficult to apply to long-term climate simulations.

9.2.2 Ensemble Approaches for Model Evaluation

Ensemble methods are used to explore the uncertainty in climate model simulations that arise from internal variability, boundary conditions, parameter values for a given model structure or structural uncertainty due to different model formulations (Tebaldi and Knutti, 2007; Hawkins and Sutton, 2009; Knutti et al., 2010a). Since the AR4, techniques have been designed to specifically evaluate model performance of individual ensemble members. Although this is typically done to better characterize uncertainties, the methods and insights are applicable to model evaluation in general. The ensembles are generally

of two types: Multi-model Ensembles (MMEs) and Perturbed Parameter (or Physics) Ensembles (PPEs).

9.2.2.1 Multi-Model Ensembles

The MME is created from existing model simulations from multiple climate modelling centres. MMEs sample structural uncertainty and internal variability. However, the sample size of MMEs is small, and is confounded because some climate models have been developed by sharing model components leading to shared biases (Masson and Knutti, 2011a). Thus, MME members cannot be treated as purely independent, which implies a reduction in the effective number of independent models (Tebaldi and Knutti, 2007; Jun et al., 2008; Knutti, 2010; Knutti et al., 2010a; Pennell and Reichler, 2011).

9.2.2.2 Perturbed-Parameter Ensembles

In contrast, PPEs are created to assess uncertainty based on a single model and benefit from the explicit control on parameter perturbations. This allows statistical methods to determine which parameters are the main drivers of uncertainty across the ensemble (e.g., Rougier et al., 2009). PPEs have been used frequently in simpler models such as EMICs (Xiao et al., 1998; Forest et al., 2002, 2006, 2008; Stott and Forest, 2007; Knutti and Tomassini, 2008; Sokolov et al., 2009; Loutre et al., 2011) and are now being applied to more complex models (Murphy et al., 2004; Annan et al., 2005; Stainforth et al., 2005; Collins et al., 2006a, 2007; Jackson et al., 2008a; Brierley et al., 2010; Klocke et al., 2011; Lambert et al., 2012). The disadvantage of PPEs is that they do not explore structural uncertainty, and thus the estimated uncertainty will depend on the underlying model that is perturbed (Yokohata et al., 2010) and may be too narrow (Sakaguchi et al., 2012). Several studies (Sexton et al., 2012; Sanderson, 2013) recognize the importance of sampling both parametric and structural uncertainty by combining information from both MMEs and PPEs. However, even these approaches cannot account for the effect on uncertainty of systematic errors.

9.2.2.3 Statistical Methods Applied to Ensembles

The most common approach to characterize MME results is to calculate the arithmetic mean of the individual model results, referred to as an unweighted multi-model mean. This approach of 'one vote per model' gives equal weight to each climate model regardless of (1) how many simulations each model has contributed, (2) how interdependent the models are or (3) how well each model has fared in objective evaluation. The multi-model mean will be used often in this chapter. Some climate models share a common lineage and so share common biases (Frame et al., 2005; Tebaldi and Knutti, 2007; Jun et al., 2008; Knutti, 2010; Knutti et al., 2010a, 2013; Annan and Hargreaves, 2011; Pennell and Reichler, 2011; Knutti and Sedlácek, 2013). As a result, collections such as the CMIP5 MME cannot be considered a random sample of independent models. This complexity creates challenges for how best to make quantitative inferences of future climate as discussed further in Chapter 12 (Knutti et al., 2010a; Collins et al., 2012; Stephenson et al., 2012; Sansom et al., 2013).

Annan and Hargreaves (2010) have proposed a 'rank histogram' approach to evaluate model ensembles as a whole, rather than individual models, by diagnosing whether observations can be considered statistically indistinguishable from a model ensemble. Studies based on this approach have suggested that MMEs (CMIP3/5) are 'reliable' in that they are not too narrow or too dispersive as a sample of possible models, but existing single-model-based ensembles tend to be too narrow (Yokohata et al., 2012, 2013). Although initial work has analysed the current mean climate state, further work is required to study the relationships between simulation errors and uncertainties in ensembles of future projections (Collins et al., 2012).

Bayesian methods offer insights into how to account for model inadequacies and combine information from several metrics in both MME and PPE approaches (Sexton and Murphy, 2012; Sexton et al., 2012), but they are complex. A simpler strategy of screening out some model variants on the basis of some observational comparison has been used with some PPEs (Lambert et al., 2012; Shiogama et al., 2012). Edwards et al. (2011) provided a statistical framework for 'pre-calibrating' out such poor model variants. Screening techniques have also been used with MMEs (Santer et al., 2009).

Additional Bayesian methods are applied to the MMEs so that past model performance is combined with prior distributions to estimate uncertainty from the MME (Furrer et al., 2007; Tebaldi and Knutti, 2007; Milliff et al., 2011). Similar to Bayesian PPE methods, common biases can be assessed within the MME to determine effective independence of the climate models (Knutti et al., 2013) (see Section 12.2.2 for a discussion of the assumptions in the Bayesian approaches).

9.2.3 The Model Evaluation Approach Used in this Chapter and Its Limitations

This chapter applies a variety of evaluation techniques ranging from visual comparison of observations and the multi-model ensemble and its mean, to application of quantitative performance metrics (see Section 9.2.2). No individual evaluation technique or performance measure is considered superior; rather, it is the combined use of many techniques and measures that provides a comprehensive overview of model performance.

Although crucial, the evaluation of climate models based on past climate observations has some important limitations. By necessity, it is limited to those variables and phenomena for which observations exist. Table 9.3 provides an overview of the observations used in this chapter. In many cases, the lack or insufficient quality of long-term observations, be it a specific variable, an important processes, or a particular region (e.g., polar areas, the upper troposphere/lower stratosphere (UTLS), and the deep ocean), remains an impediment. In addition, owing to observational uncertainties and the presence of internal variability, the observational record against which models are assessed is 'imperfect'. These limitations can be reduced, but not entirely eliminated, through the use of multiple independent observations of the same variable as well as the use of model ensembles.

The approach to model evaluation taken in the chapter reflects the need for climate models to represent the observed behaviour of past climate as a necessary condition to be considered a viable tool for future projections. This does not, however, provide an answer to

the much more difficult question of determining how well a model must agree with observations before projections made with it can be deemed reliable. Since the AR4, there are a few examples of emergent constraints where observations are used to constrain multi-model ensemble projections. These examples, which are discussed further in Section 9.8.3, remain part of an area of active and as yet inconclusive research.

Table 9.3 | Overview of observations that are used to evaluate climate models in this chapter. The quantity and CMIP5 output variable name are given along with references for the observations. Superscript (1) indicates this observations-based data set is obtained from atmospheric reanalysis. Superscript (D) indicates default reference; superscript (A) alternate reference.

9.3 Experimental Strategies in Support of Climate Model Evaluation

9.3.1 The Role of Model Intercomparisons

Systematic model evaluation requires a coordinated and well-documented suite of model simulations. Organized Model Intercomparison Projects (MIPs) provide this via standard or benchmark experiments that represent critical tests of a model's ability to simulate the observed climate. When modelling centres perform a common experiment, it offers the possibility to compare their results not just with observations, but with other models as well. This intercomparison enables researchers to explore the range of model behaviours, to isolate the various strengths and weaknesses of different models in a controlled setting, and to interpret, through idealized experiments, the inter-model differences. Benchmark MIP experiments offer a way to distinguish between errors particular to an individual model and those that might be more universal and should become priority targets for model improvement.

9.3.2 Experimental Strategy for Coupled Model Intercomparison Project Phase 5

9.3.2.1 Experiments Utilized for Model Evaluation

CMIP5 includes a much more comprehensive suite of model experiments than was available in the preceding CMIP3 results assessed in the AR4 (Meehl et al., 2007). In addition to a better constrained specification of historical forcing, the CMIP5 collection also includes initialized decadal-length predictions and long-term experiments using both ESMs and AOGCMs (Taylor et al., 2012b) (Figure 9.1). The CO_2 forcing of these experiments is prescribed as a time series of either global mean concentrations or spatially resolved anthropogenic emissions (Section 9.3.2.2). The analyses of model performance in this chapter are based on the concentration-based experiments with the exception of the evaluation of the carbon cycle (see Section 9.4.5).

Most of the model diagnostics are derived from the historical simulations that span the period 1850– 2005. In some cases, these historical simulations are augmented by results from a scenario run, either RCP4.5 or RCP8.5 (see Section 9.3.2.2), so as to facilitate comparison with more recent observations. CMIP5/Paleoclimate Modelling Intercomparison Project version 3 (PMIP3) simulations for the mid-Holocene and last glacial maximum are used to evaluate model response to palaeoclimatic conditions. Historical emissions-driven simulations are used to evaluate the prognostic carbon cycle. The analysis of global surface temperature variability is based in part on long pre-industrial control runs to facilitate calculation of variability on decadal to centennial time scales. Idealized simulations with 1% per year increases in CO_2 are utilized to derive transient climate response. Equilibrium climate sensitivities are derived using results of specialized experiments, with fourfold CO_2 increase, designed specifically for this purpose.

9.3.2.2 Forcing of the Historical Experiments

Under the protocols adopted for CMIP5 and previous assessments, the transient climate experiments are conducted in three phases. The first phase covers the start of the modern industrial period through to the present day, years 1850–2005 (van Vuuren et al., 2011). The second phase covers the future, 2006–2100, and is described by a collection of RCPs (Moss et al., 2010). As detailed in Chapter 12, the third phase is described by a corresponding collection of Extension Concentration

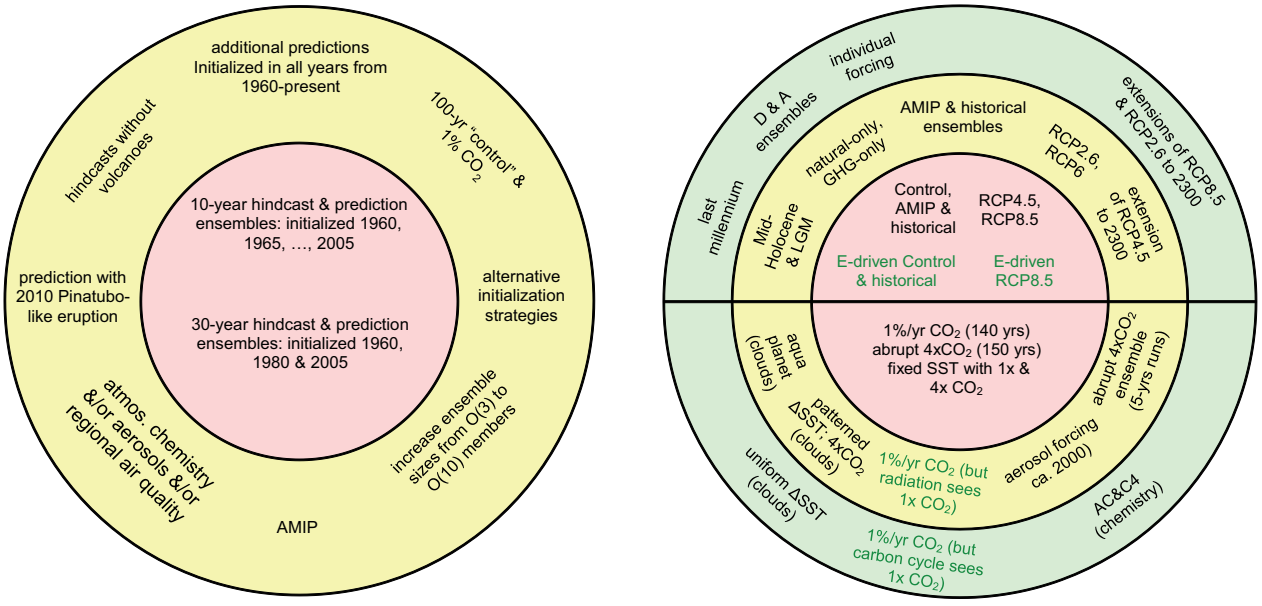

Figure 9.1 | Left: Schematic summary of CMIP5 short-term experiments with tier 1 experiments (yellow background) organized around a central core (pink background). (From Taylor et al., 2012b, their Figure 2). Right: Schematic summary of CMIP5 long-term experiments with tier 1 experiments (yellow background) and tier 2 experiments (green background) organized around a central core (pink background). Green font indicates simulations to be performed only by models with carbon cycle representations, and 'E-driven' means 'emission-driven'. Experiments in the upper semicircle either are suitable for comparison with observations or provide projections, whereas those in the lower semicircle are either idealized or diagnostic in nature, and aim to provide better understanding of the climate system and model behaviour. (From Taylor et al., 2012b, their Figure 3.)

Pathways (Meinshausen et al., 2011). The forcings for the historical simulations evaluated in this section and are described briefly here (with more details in Annex II).

In the CMIP3 20th century experiments, the forcings from radiatively active species other than long-lived GHGs and sulphate aerosols were left to the discretion of the individual modelling groups (IPCC, 2007). By contrast, a comprehensive set of historical anthropogenic emissions and land use and land cover change data have been assembled for the CMIP5 experiments in order to produce a relatively homogeneous ensemble of historical simulations with common time series of forcing agents. Emissions of natural aerosols including soil dust, sea salt and volcanic species are still left to the discretion of the individual modelling groups.

For AOGCMs without chemical and biogeochemical cycles, the forcing agents are prescribed as a set of concentrations. The concentrations for GHGs and related compounds include CO_2, CH_4, N_2O, all fluorinated gases controlled under the Kyoto Protocol (hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulphur hexafluoride (SF_6)), and ozone-depleting substances controlled under the Montreal Protocol (chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), Halons, carbon tetrachloride (CCl_4), methyl bromide (CH_3Br), methyl chloride (CH_3Cl)). The concentrations for aerosol species include sulphate (SO_4), ammonium nitrate (NH_4NO_3), hydrophobic and hydrophilic black carbon, hydrophobic and hydrophilic organic carbon, secondary organic aerosols (SOAs) and four size categories of dust and sea salt. For ESMs that include chemical and biogeochemical cycles, the forcing agents are prescribed both as a set of concentrations and as a set of emissions with provisions to separate the forcing by natural and anthropogenic CO_2 (Hibbard et al., 2007). The emissions include time-dependent spatially resolved fluxes of CH_4, NO_X, CO, NH_3, black and organic carbon, and volatile organic compounds (VOCs). For models that treat the chemical processes associated with biomass burning, emissions of additional species such as C_2H_4O (acetaldehyde), C_2H_5OH (ethanol), C_2H_6S (dimethylsulphide) and C_3H_6O (acetone) are also prescribed. Historical land use and land cover change is described in terms of the time-evolving partitioning of land surface area among cropland, pasture, primary land and secondary (recovering) land, including the effects of wood harvest and shifting cultivation, as well as land use changes and transitions from/to urban land (Hurtt et al., 2009). These emissions data are aggregated from empirical reconstructions of grassland and forest fires (Schultz et al., 2008; Mieville et al., 2010); international shipping (Eyring et al., 2010); aviation (Lee et al., 2009), sulphur (Smith et al., 2011b), black and organic carbon (Bond et al., 2007); and NO_X, CO, CH_4 and non methane volatile organic compounds (NMVOCs) (Lamarque et al., 2010) contributed by all other sectors.

For the natural forcings a recommended monthly averaged total solar irradiance time series was given, but there was no recommended treatment of volcanic forcing. Both integrated solar irradiance and its spectrum were available, but not all CMIP5 models used the spectral data. The data employed an 1850-2008 reconstruction of the solar cycle and its secular trend using observations of sunspots and faculae, the 10.7 cm solar irradiance measurements and satellite observations (Frohlich and Lean, 2004).For volcanic forcing CMIP5 models typically employed one of two prescribed volcanic aerosol data sets (Sato et al., 1993) or (Ammann et al., 2003) but at least one ESM employed interactive aerosol injection (Driscoll et al., 2012). The prescribed data sets did not incorporate injection from explosive volcanoes after 2000.

9.3.2.3 Relationship of Decadal and Longer-Term Simulations

The CMIP5 archive also includes a new class of decadal-prediction experiments (Meehl et al., 2009, 2013b) (Figure 9.1). The goal is to understand the relative roles of forced changes and internal variability in historical and near-term climate variables, and to assess the predictability that might be realized on decadal time scales. These experiments comprise two sets of hindcast and prediction ensembles with initial conditions spanning 1960 through 2005. The set of 10-year ensembles are initialized starting at 1960 in 1-year increments through the year 2005 while the 30-year ensembles are initialized at 1960, 1980 and 2005. The same physical models are often used for both the short-term and long-term experiments (Figure 9.1) despite the different initialization of these two sets of simulations. Results from the short-term experiments are described in detail in Chapter 11.

9.4 Simulation of Recent and Longer-Term Records in Global Models

9.4.1 Atmosphere

Many aspects of the atmosphere have been more extensively evaluated than other climate model components. One reason is the availability of near-global observationally based data for energy fluxes at the TOA, cloud cover and cloud condensate, temperature, winds, moisture, ozone and other important properties. As discussed in Box 2.3, atmospheric reanalyses have also enabled integrating independent observations in a physically consistent manner. In this section we use this diversity of data (see Table 9.3) to evaluate the large-scale atmospheric behaviour.

9.4.1.1 Temperature and Precipitation Spatial Patterns of the Mean State

Surface temperature is perhaps the most routinely examined quantity in atmospheric models. Many processes must be adequately represented in order for a model to realistically capture the observed temperature distribution. The dominant external influence is incoming solar radiation, but many aspects of the simulated climate play an important role in modulating regional temperature such as the presence of clouds and the complex interactions between the atmosphere and the underlying land, ocean, snow, ice and biosphere.

The annual mean surface air temperature (at 2 m) is shown in Figure 9.2(a) for the mean of all available CMIP5 models, and the error, relative to an observationally constrained reanalysis (ECMWF reanalysis of the global atmosphere and surface conditions (ERA)-Interim; Dee et al., 2011) is shown in Figure 9.2(b). In most areas the multi-model mean agrees with the reanalysis to within 2°C, but there are several locations where the biases are much larger, particularly at high elevations over the Himalayas and parts of both Greenland and Antarctica, near the ice edge in the North Atlantic, and over ocean upwelling regions

off the west coasts of South America and Africa. Averaging the absolute error of the individual CMIP5 models (Figure 9.2c) yields similar magnitude as the multi-model mean bias (Figure 9.2b), implying that compensating errors across models is limited. The inconsistency across the three available global reanalyses (Figure 9.2d) that have assimilated temperature data at two metres (Onogi et al., 2007; Simmons et al., 2010) provides an indication of observational uncertainty. Although the reanalysis inconsistency is smaller than the mean absolute bias in almost all regions, areas where inconsistency is largest (typically where observations are sparse) tend to be the same regions where the CMIP5 models show largest mean absolute error.

Seasonal performance of models can be evaluated by examining the difference between means for December–January–February (DJF) and June–July–August (JJA). Figures 9.3(a) and (b) show the CMIP5 mean model seasonal cycle amplitude in surface air temperature (as measured by the difference between the DJF and JJA and the absolute value of this difference). The seasonal cycle amplitude is much larger over land where the thermal inertia is much smaller than over the oceans, and it is generally larger at higher latitudes as a result of the larger seasonal amplitude in insolation. Figures 9.3(c) and (d) show the mean model bias of the seasonal cycle relative to the ERA-Interim reanalysis (Dee et al., 2011). The largest biases correspond to areas of large seasonal amplitude, notably high latitudes over land, but relatively large biases are also evident in some lower latitude regions such as over northern India. Over most land areas the amplitude of the modelled seasonal cycle is larger than observed, whereas over much of the extratropical oceans the modelled amplitude is too small.

The simulation of precipitation is a more stringent test for models as it depends heavily on processes that must be parameterized. Challenges are compounded by the link to surface fields (topography, coastline, vegetation) that lead to much greater spatial heterogeneity at regional scales. Figure 9.4 shows the mean precipitation rate simulated by the CMIP5 multi-model ensemble, along with measures of error relative to precipitation analyses from the Global Precipitation Climatology Project (Adler et al., 2003). The magnitude of observational uncertainty for precipitation varies with region, which is why many studies make use

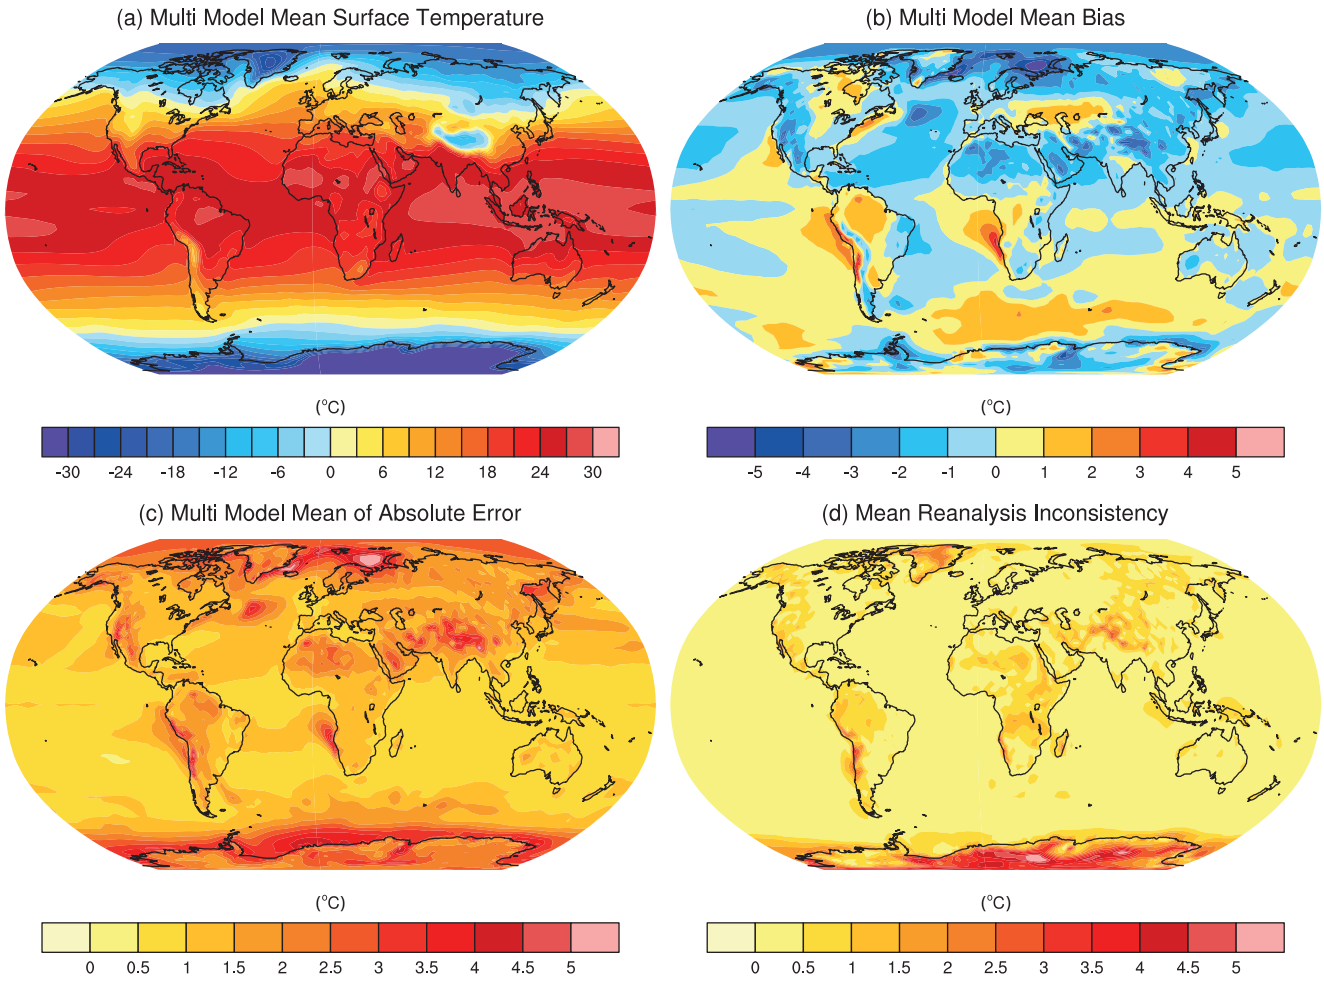

Figure 9.2 | Annual-mean surface (2 m) air temperature (°C) for the period 1980–2005. (a) Multi-model (ensemble) mean constructed with one realization of all available models used in the CMIP5 historical experiment. (b) Multi-model-mean bias as the difference between the CMIP5 multi-model mean and the climatology from ECMWF reanalysis of the global atmosphere and surface conditions (ERA)-Interim (Dee et al., 2011); see Table 9.3. (c) Mean absolute model error with respect to the climatology from ERA-Interim. (d) Mean inconsistency between ERA-Interim, ERA 40-year reanalysis (ERA40) and Japanese 25-year ReAnalysis (JRA-25) products as the mean of the absolute pairwise differences between those fields for their common period (1979–2001).

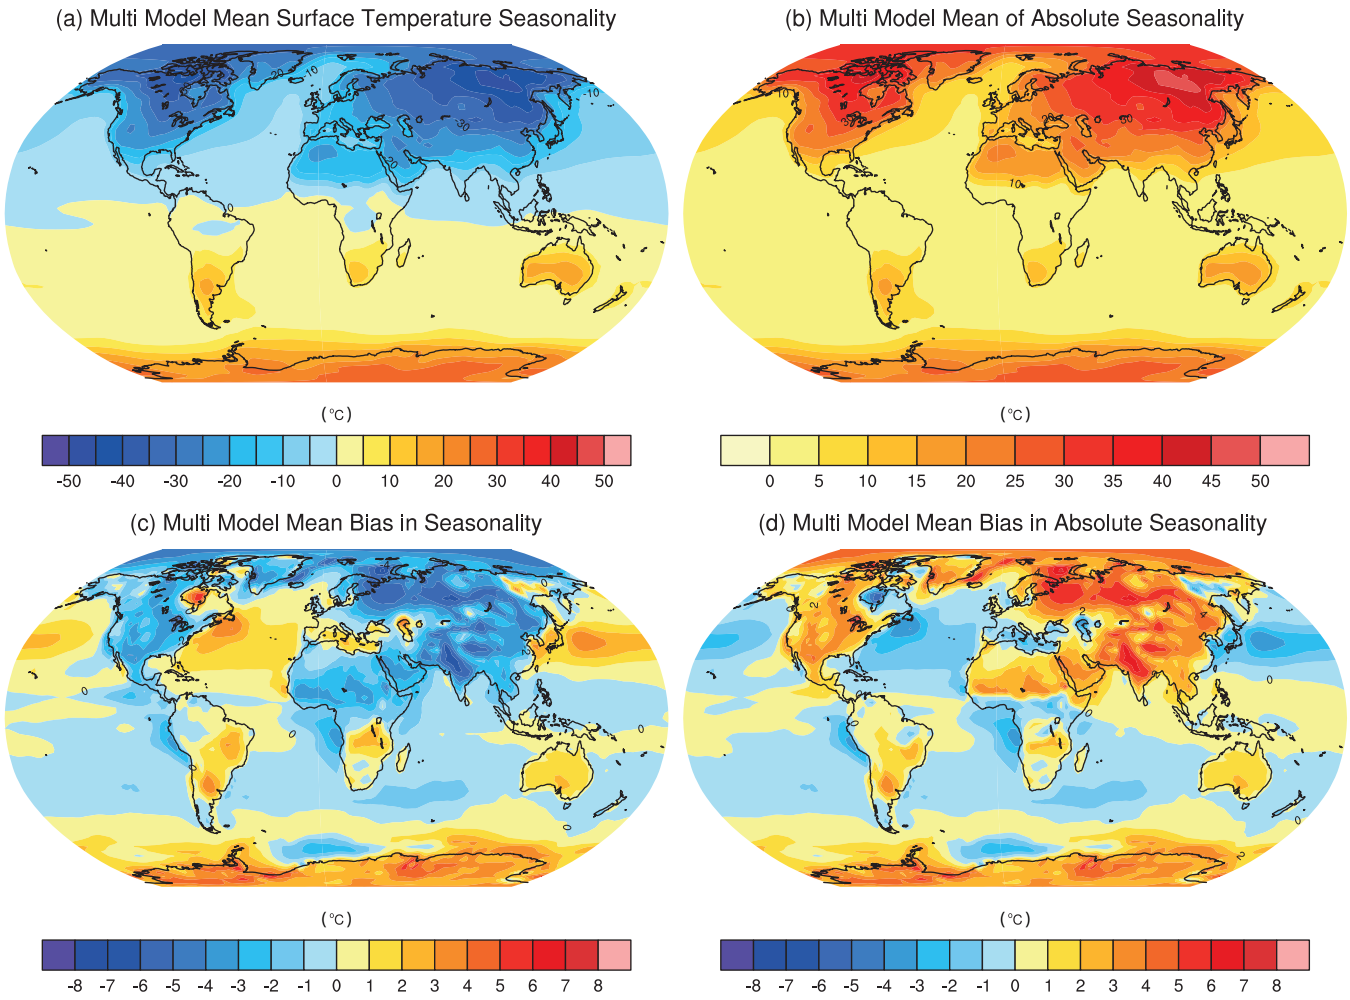

Figure 9.3 | Seasonality (December–January–February minus June–July–August) of surface (2 m) air temperature (°C) for the period 1980–2005. (a) Multi-model mean, calculated from one realization of all available CMIP5 models for the historical experiment. (b) Multi-model mean of absolute seasonality. (c) Difference between the multi-model mean and the ECMWF reanalysis of the global atmosphere and surface conditions (ERA)-Interim seasonality. (d) Difference between the multi-model mean and the ERA-Interim absolute seasonality.

of several estimates of precipitation. Known large-scale features are reproduced by the multi-model mean, such as a maximum precipitation just north of the equator in the central and eastern tropical Pacific, dry areas over the eastern subtropical ocean basins, and the minimum rainfall in Northern Africa (Dai, 2006). While many large-scale features of the tropical circulation are reasonably well simulated, there are persistent biases. These include too low precipitation along the equator in the Western Pacific associated with ocean–atmosphere feedbacks maintaining the equatorial cold tongue (Collins et al., 2010) and excessive precipitation in tropical convergence zones south of the equator in the Atlantic and the Eastern Pacific (Lin, 2007; Pincus et al., 2008). Other errors occurring in several models include an overly zonal orientation of the South-Pacific Convergence Zone (Brown et al., 2013) as well as an overestimate of the frequency of occurrence of light rain events (Stephens et al., 2010). Regional-scale precipitation simulation has strong parameter dependence (Rougier et al., 2009; Chen et al., 2010; Neelin et al., 2010), and in some models substantial improvements have been shown through increases in resolution (Delworth et al., 2012) and improved representations of sub-gridscale processes, particularly convection (Neale et al., 2008). Judged by similarity with the spatial pattern of observations, the overall quality of the simulation of the mean state of precipitation in the CMIP5 ensemble is slightly better than in the CMIP3 ensemble (see FAQ 9.1 and Figure 9.6).

In summary, there is *high confidence* that large-scale patterns of surface temperature are well simulated by the CMIP5 models. In certain regions this agreement with observations is limited, particularly at elevations over the Himalayas and parts of both Greenland and Antarctica. The broad-scale features of precipitation as simulated by the CMIP5 models are in modest agreement with observations, but there are systematic errors in the Tropics.

9.4.1.2 Atmospheric Moisture, Clouds and Radiation

The global annual mean precipitable water is a measure of the total moisture content of the atmosphere. For the CMIP3 ensemble, the values of precipitable water agreed with one another and with multiple estimates from the National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR) and ECMWF

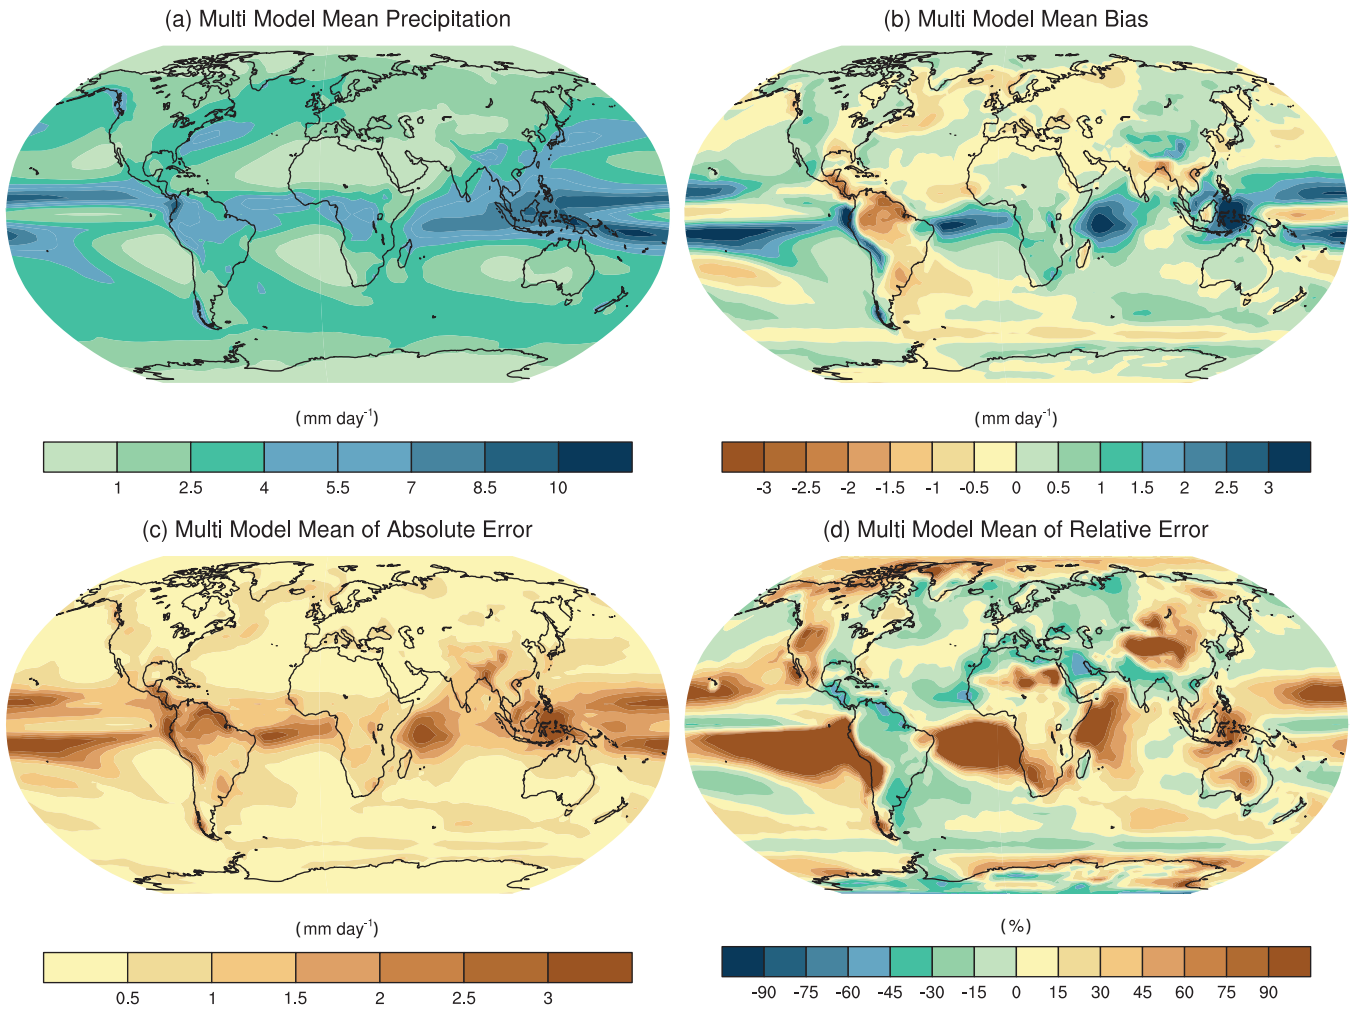

Figure 9.4 | Annual-mean precipitation rate (mm day^{-1}) for the period 1980–2005. (a) Multi-model-mean constructed with one realization of all available AOGCMs used in the CMIP5 historical experiment. (b) Difference between multi-model mean and precipitation analyses from the Global Precipitation Climatology Project (Adler et al., 2003). (c) Multi-model-mean absolute error with respect to observations. (d) Multi-model-mean error relative to the multi-model-mean precipitation itself.

ERA40 meteorological reanalyses to within approximately 10% (Walisser et al., 2007). Initial analysis of the CMIP5 ensemble shows the model results are within the uncertainties of the observations (Jiang et al., 2012a).

Modelling the vertical structure of water vapour is subject to greater uncertainty since the humidity profile is governed by a variety of processes. The CMIP3 models exhibited a significant dry bias of up to 25% in the boundary layer and a significant moist bias in the free troposphere of up to 100% (John and Soden, 2007). Upper tropospheric water vapour varied by a factor of three across the multi-model ensemble (Su et al., 2006). Many models have large biases in lower stratospheric water vapour (Gettelman et al., 2010), which could have implications for surface temperature change (Solomon et al., 2010). The limited number of studies available for the CMIP5 model ensemble broadly confirms the results from the earlier model generation. In tropical regions, the models are too dry in the lower troposphere and too moist in the upper troposphere, whereas in the extratropics they are too moist throughout the troposphere (Tian et al., 2013). However, many of the model values lie within the observational uncertainties. Jiang et al. (2012a) show that the largest biases occur in the upper troposphere, with model values up to twice that observed, while in the middle and lower troposphere models simulate water vapour to within 10% of the observations.

The spatial patterns and seasonal cycle of the radiative fluxes at the TOA are fundamental energy balance quantities. Both the CMIP3 and CMIP5 model ensembles reproduce these patterns with considerable fidelity relative to the National Aeronautics and Space Adminsitration (NASA) Clouds and the Earth's Radiant Energy System (CERES) data sets (Pincus et al., 2008; Wang and Su, 2013). Globally averaged TOA shortwave and longwave components of the radiative fluxes in 12 atmosphere-only versions of the CMIP5 models were within 2.5 W m^{-2} of the observed values (Wang and Su, 2013).

Comparisons against surface components of radiative fluxes show that, on average, the CMIP5 models overestimate the global mean downward all-sky shortwave flux at the surface by 2 ± 6 W m^{-2} (1 ± 3%) and underestimate the global downward longwave flux by 6 ± 9 W m^{-2} (2 ± 2%) (Stephens et al., 2012). Although in tropical regions

between 1 and 3 W m^{-2} of the bias may be due to systematic omission of precipitating and/or convective core ice hydrometeors (Waliser et al., 2011), the correlation between the biases in the all-sky and clear-sky downwelling fluxes suggests that systematic errors in clear-sky radiative transfer calculations may be a primary cause for these biases. This is consistent with an analysis of the global annual mean estimates of clear-sky atmospheric absorption from the CMIP3 ensemble and the systematic underestimation of clear-sky solar absorption by radiative transfer codes (Oreopoulos et al., 2012). The underestimation of absorption can be attributed to the omission or underestimation of

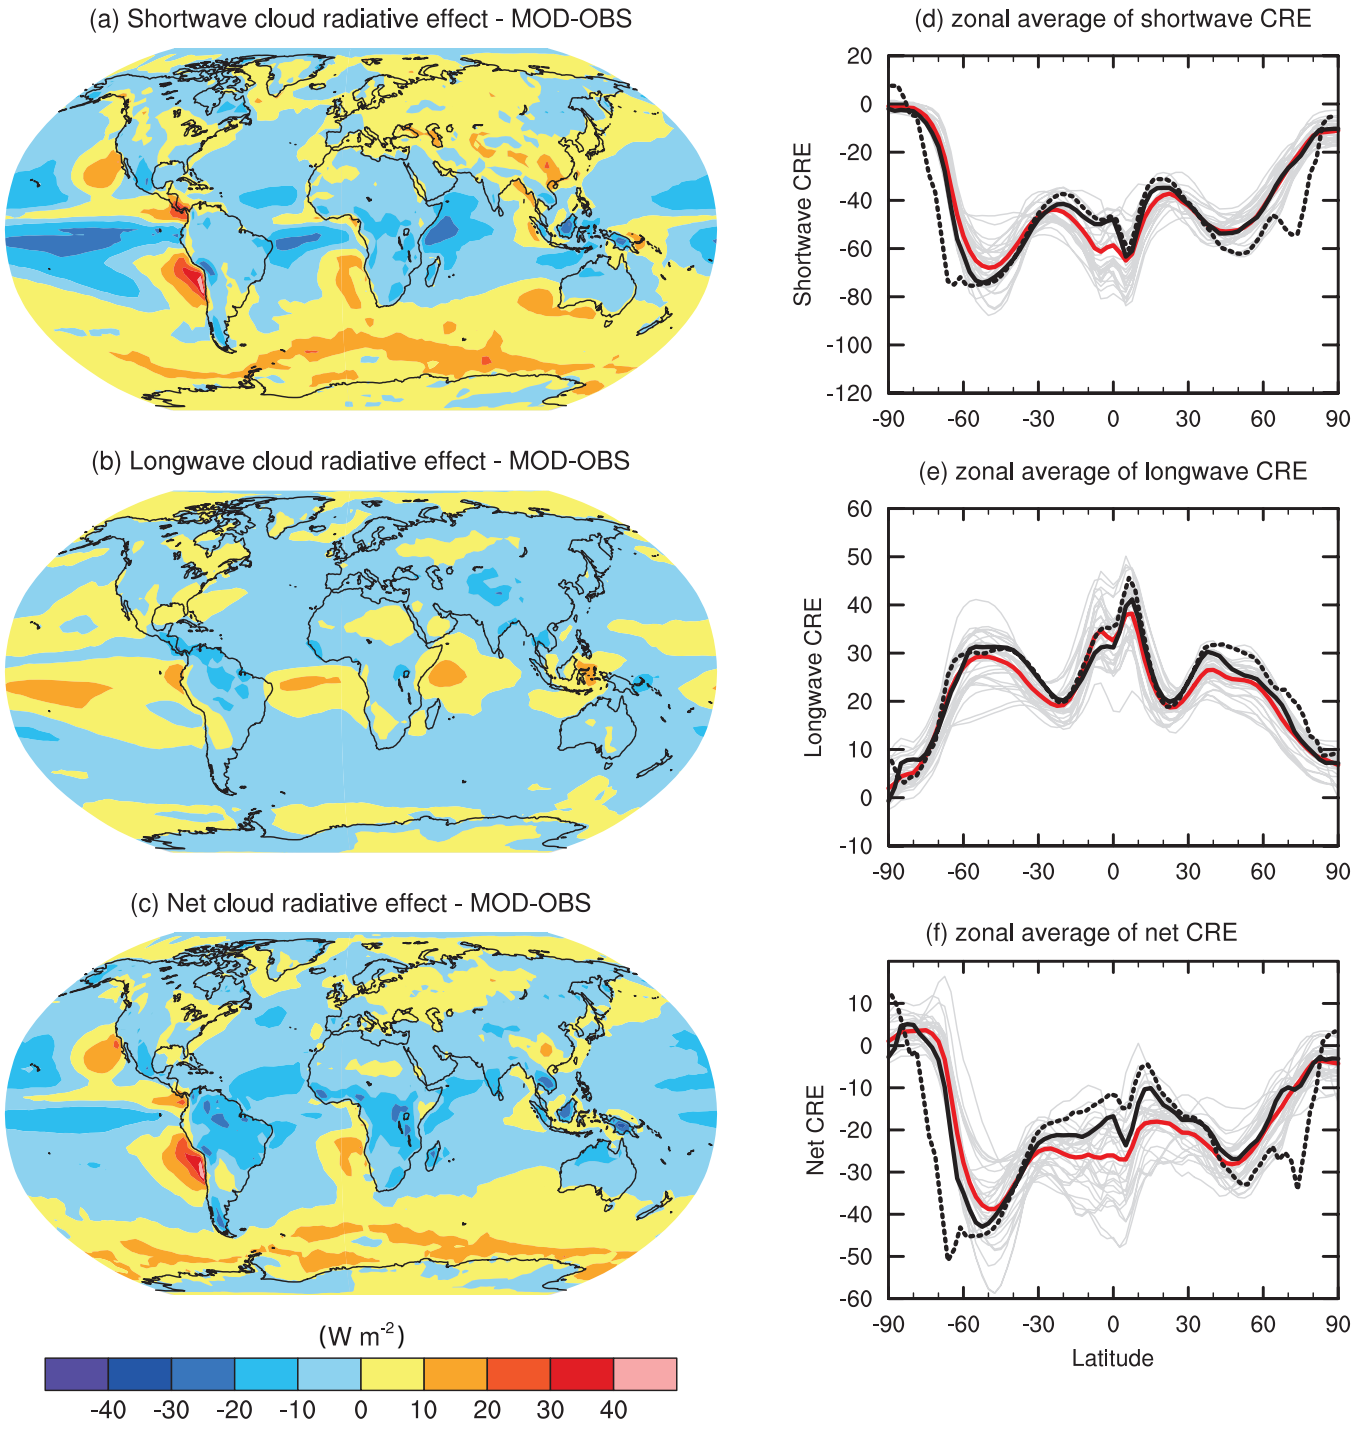

Figure 9.5 | Annual-mean cloud radiative effects of the CMIP5 models compared against the Clouds and the Earth's Radiant Energy System Energy Balanced and Filled 2.6 (CERES EBAF 2.6) data set (in W m^{-2}; top row: shortwave effect; middle row: longwave effect; bottom row: net effect). On the left are the global distributions of the multi-model-mean biases, and on the right are the zonal averages of the cloud radiative effects from observations (solid black: CERES EBAF 2.6; dashed black: CERES ES-4), individual models (thin grey lines), and the multi-model mean (thick red line). Model results are for the period 1985–2005, while the available CERES data are for 2001–2011. For a definition and maps of cloud radiative effect, see Section 7.2.1.2 and Figure 7.7.

absorbing aerosols, in particular carbonaceous species (Kim and Ramanathan, 2008), or to the omission of weak-line (Collins et al., 2006b) or continuum (Ptashnik et al., 2011) absorption by water vapour (Wild et al., 2006).

One of the major influences on radiative fluxes in the atmosphere is the presence of clouds and their radiative properties. To measure the influence of clouds on model deficiencies in the TOA radiation budget, Figure 9.5 shows maps of deviations from observations in annual mean shortwave (top left), longwave (middle left) and net (bottom left) cloud radiative effect (CRE) for the CMIP5 multi-model mean. The figure (right panels) also shows zonal averages of the same quantities from two sets of observations, the individual CMIP5 models, and the multi-model average. The definition of CRE and observed mean fields for these quantities can be found in Chapter 7 (Section 7.2.1.2, Figure 7.7).

Models show large regional biases in CRE in the shortwave component, and these are particularly pronounced in the subtropics with too weak an effect (positive error) of model clouds on shortwave radiation in the stratocumulus regions and too strong an effect (negative error) in the trade cumulus regions. This error has been shown to largely result from an overestimation of cloud reflectance, rather than cloud cover (Nam et al., 2012). A too weak cloud influence on shortwave radiation is evident over the subpolar oceans of both hemispheres and the Northern Hemisphere (NH) land areas. It is evident in the zonal mean graphs that there is a wide range in both longwave and shortwave CRE between individual models. As is also evident, a significant reduction in the difference between models and observations has resulted from changes in the observational estimates of CRE, in particular at polar and subpolar as well as subtropical latitudes (Loeb et al., 2009).

Understanding the biases in CRE in models requires a more in-depth analysis of the biases in cloud properties, including the fractional coverage of clouds, their vertical distribution as well as their liquid water and ice content. Major progress in this area has resulted from both the availability of new observational data sets and improved diagnostic techniques, including the increased use of instrument simulators (e.g., Cesana and Chepfer, 2012; Jiang et al., 2012a). Many models have particular difficulties simulating upper tropospheric clouds (Jiang et al., 2012a), and low and mid-level cloud occurrence are frequently underestimated (Cesana and Chepfer, 2012; Nam et al., 2012; Tsushima et al., 2013). Global mean values of both simulated ice and liquid water path vary by factors of 2 to 10 between models (Jiang et al., 2012a; Li et al., 2012a). The global mean fraction of clouds that can be detected with confidence from satellites (optical thickness >1.3, Pincus et al. (2012)) is underestimated by 5 to 10 % (Klein et al., 2013). Some of the above errors in clouds compensate to provide the global mean balance in radiation required by model tuning (Tsushima et al., 2013; Wang and Su, 2013; Box 9.1).

In-depth analysis of several global and regional models (Karlsson et al., 2008; Teixeira et al., 2011) has shown that the interaction of boundary layer and cloud processes with the larger scale circulation systems that ultimately drive the observed subtropical cloud distribution remains poorly simulated. Large errors in subtropical clouds have been shown to negatively affect SST patterns in coupled model simulations (Hu

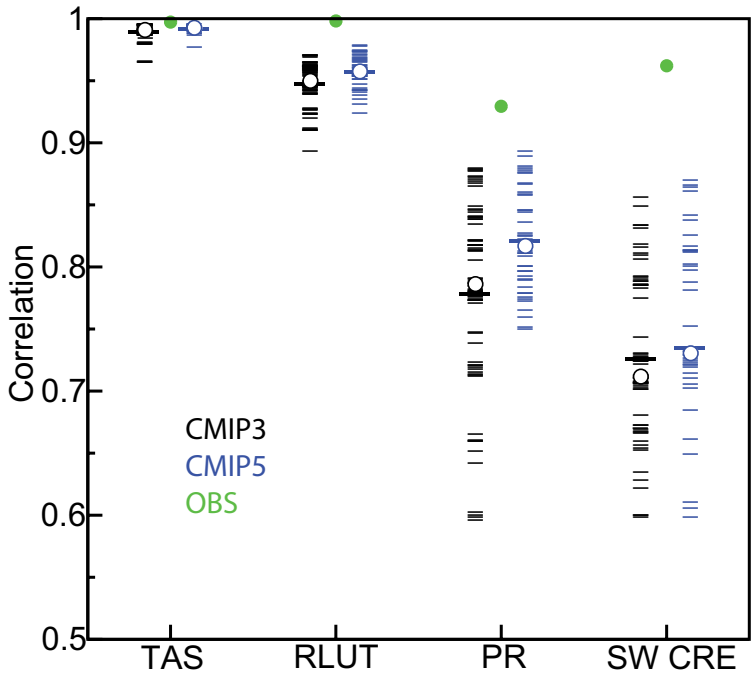

Figure 9.6 | Centred pattern correlations between models and observations for the annual mean climatology over the period 1980–1999. Results are shown for individual CMIP3 (black) and CMIP5 (blue) models as thin dashes, along with the corresponding ensemble average (thick dash) and median (open circle). The four variables shown are surface air temperature (TAS), top of the atmosphere (TOA) outgoing longwave radiation (RLUT), precipitation (PR) and TOA shortwave cloud radiative effect (SW CRE). The observations used for each variable are the default products and climatological periods identified in Table 9.3. The correlations between the default and alternate (Table 9.3) observations are also shown (solid green circles). To ensure a fair comparison across a range of model resolutions, the pattern correlations are computed at a resolution of 4° in longitude and 5° in latitude. Only one realization is used from each model from the CMIP3 20C3M and CMIP5 historical simulations.

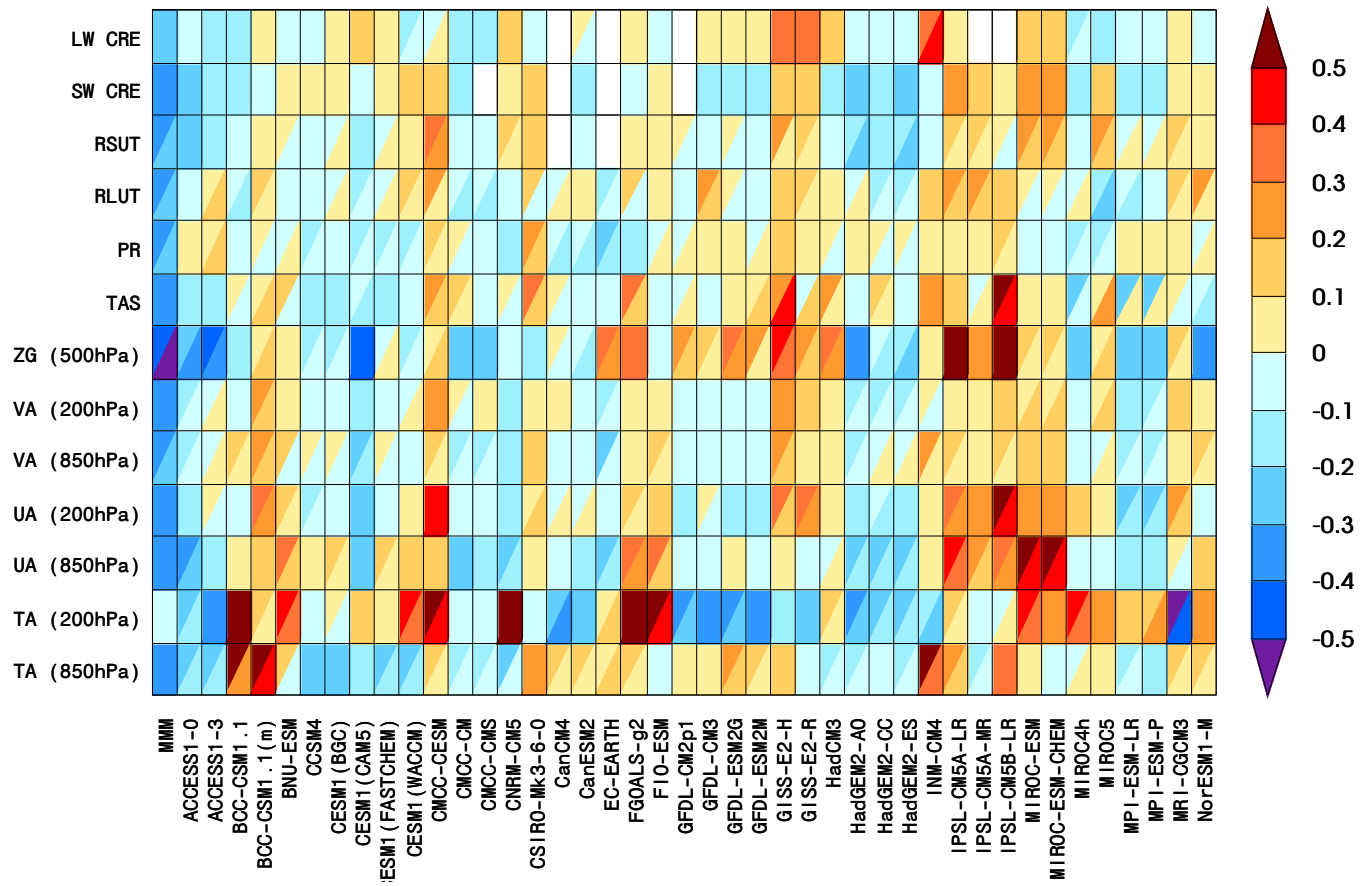

Figure 9.7 | Relative error measures of CMIP5 model performance, based on the global seasonal-cycle climatology (1980–2005) computed from the historical experiments. Rows and columns represent individual variables and models, respectively. The error measure is a space–time root-mean-square error (RMSE), which, treating each variable separately, is portrayed as a relative error by normalizing the result by the median error of all model results (Gleckler et al., 2008). For example, a value of 0.20 indicates that a model's RMSE is 20% larger than the median CMIP5 error for that variable, whereas a value of –0.20 means the error is 20% smaller than the median error. No colour (white) indicates that model results are currently unavailable. A diagonal split of a grid square shows the relative error with respect to both the default reference data set (upper left triangle) and the alternate (lower right triangle). The relative errors are calculated independently for the default and alternate data sets. All reference data used in the diagram are summarized in Table 9.3.

et al., 2011; Wahl et al., 2011). Several studies have highlighted the potential importance and poor simulation of subpolar clouds in the Arctic and Southern Oceans (Karlsson and Svensson, 2010; Trenberth and Fasullo, 2010b; Haynes et al., 2011; Bodas-Salcedo et al., 2012). A particular challenge for models is the simulation of the correct phase of the cloud condensate, although very few observations are available to evaluate models particularly with respect to their representation of cloud ice (Waliser et al., 2009b; Li et al., 2012a). Regime-oriented approaches to the evaluation of model clouds (see Section 9.2.1) have identified that compensating errors in the CRE are largely a result of misrepresentations of the frequency of occurrence of key observed cloud regimes, while the radiative properties of the individual regimes contribute less to the overall model deficiencies (Tsushima et al., 2013).

Several studies have identified progress in the simulation of clouds in the CMIP5 models compared to their CMIP3 counterparts. Particular examples include the improved simulation of vertically integrated ice water path (Jiang et al., 2012a; Li et al., 2012a) as well as a reduction of overabundant optically thick clouds in the mid-latitudes (Klein et al., 2013; Tsushima et al., 2013).

In summary, despite modest improvements there remain significant errors in the model simulation of clouds. There is *very high confidence* that these errors contribute significantly to the uncertainties in estimates of cloud feedbacks (see Section 9.7.2.3; Section 7.2.5, Figure 7.10) and hence the spread in climate change projections reported in Chapter 12.

9.4.1.3 Quantifying Model Performance with Metrics

Performance metrics were used to some extent in the Third Assessment Report (TAR) and the Fourth Assessment Report (AR4), and are expanded upon here because of their increased appearance in the recent literature. As a simple example, Figure 9.6 illustrates how the pattern correlation between the observed and simulated climatological annual mean spatial patterns depends very much on the quantity examined. All CMIP3 and CMIP5 models capture the mean surface temperature distribution quite well, with correlations above 0.95, which are largely determined by the meridional temperature gradient. Correlations for outgoing longwave radiation are somewhat lower. For precipitation and the TOA shortwave cloud radiative effect, the correlations

between models and observations are below 0.90, and there is considerable scatter among model results. This example quantifies how some aspects of the simulated large-scale climate agree with observations better than others. Some of these differences are attributable to smoothly varying fields (e.g., temperature, water vapour) often agreeing better with observations than fields that exhibit fine structure (e.g., precipitation) (see also Section 9.6.1.1). Incremental improvement in each field is also evident in Figure 9.6, as gauged by the mean and median results in the CMIP5 ensemble having higher correlations than CMIP3. This multi-variate quantification of model improvement across development cycles is evident in several studies (e.g., Reichler and Kim, 2008; Knutti et al., 2013)

Figure 9.7 (following Gleckler et al., 2008) depicts the space–time root-mean-square error (RMSE) for the 1980–2005 climatological seasonal cycle of the historically forced CMIP5 simulations. For each of the fields examined, this 'portrait plot' depicts relative performance, with blue shading indicating performance being better, and red shading worse, than the median of all model results. In each case, two observations-based estimates are used to demonstrate the impact of the selection of reference data on the results. Some models consistently compare better with observations than others, some exhibit mixed performance and some stand out with relatively poor agreement with observations. For most fields, the choice of the observational data set does not substantially change the result for global error measures (e.g., between a state-of-the-art and an older-generation reanalysis), indicating that inter-model differences are substantially larger than the differences between the two reference data sets or the impact of two different climatological periods (e.g., for radiation fields: Earth Radiation Budget Experiment (ERBE) 1984–1988; CERES EBAF, 2001–2011). Nevertheless, it is important to recognize that different data sets often rely on the same source of measurements, and that the results in this figure can have some sensitivity to a variety of factors such as instrument uncertainty, sampling errors (e.g., limited record length of observations), the spatial scale of comparison, the domain considered and the choice of metric.

Another notable feature of Figure 9.7 is that in most cases the multi-model mean agrees more favourably with observations than any individual model. This has been long recognized to hold for surface temperature and precipitation (e.g., Lambert and Boer, 2001). However, since the AR4, it has become clear that this holds for a broad range of climatological fields (Gleckler et al., 2008; Pincus et al., 2008; Knutti et al., 2010a) and is theoretically better understood (Annan and Hargreaves, 2011). It is worth noting that when most models suffer from a common error, such as the cold bias at high latitudes in the upper troposphere (see TA 200 hPa of Figure 9.7), individual models can agree better with observations than the multi-model mean.

Correlations between the relative errors for different quantities in Figure 9.7 are known to exist, reflecting physical relationships in the model formulations and in the real world. Cluster analysis methods have recently been used in an attempt to reduce this redundancy (e.g., Yokoi et al., 2011; Nishii et al., 2012), thereby providing more succinct summaries of model performance. Some studies have attempted an overall skill score by averaging together the results from multiple metrics (e.g., Reichler and Kim, 2008). Although this averaging process is largely arbitrary, combining the results of multiple metrics can reduce the chance that a poorer performing model will score well for the wrong reasons. Recent work (Nishii et al., 2012) has demonstrated that different methods used to produce a multi-variate skill measure for the CMIP3 models did not substantially alter the conclusions about the better and lesser performing models.

Large scale performance metrics are a typical first-step toward quantifying model agreement with observations, and summarizing broad characteristics of model performance that are not focussed on a particular application. More specialized performance tests target aspects of a simulation believed to be especially important for constraining model projections, although to date the connections between particular performance metrics and reliability of future projections are not well established. This important topic is addressed in Section 9.8.3, which highlights several identified relationships between model performance and projection responses.

9.4.1.4 Long-Term Global-Scale Changes

The comparison of observed and simulated climate change is complicated by the fact that the simulation results depend on both model formulation and the time-varying external forcings imposed on the models (Allen et al., 2000; Santer et al., 2007). De-convolving the importance of model and forcing differences in the historical simulations is an important topic that is addressed in Chapter 10; however, in this section a direct comparison is made to illustrate the ability of models to reproduce past changes.

9.4.1.4.1 Global surface temperature

Figure 9.8 compares the observational record of 20th century changes in global surface temperature to that simulated by each CMIP5 and EMIC model and the respective multi-model means. The inset on the right of the figure shows the climatological mean temperature for each model, averaged over the 1961–1990 reference period. Although biases in mean temperature are apparent, there is less confidence in observational estimates of climatological temperature than in variations about this mean (Jones et al. (1999). For the CMIP5 models, interannual variability in most of the simulations is qualitatively similar to that observed although there are several exceptions. The magnitude of interannual variations in the observations is noticeably larger than the multi-model mean because the averaging of multiple model results acts to filter much of the simulated variability. On the other hand, the episodic volcanic forcing that is applied to most models (see Section 9.3.2.2) is evident in the multi-model agreement with the observed cooling particularly noticeable after the 1991 Pinatubo eruption. The gradual warming evident in the observational record, particularly in the more recent decades, is also evident in the simulations, with the multi-model mean tracking the observed value closely over most of the century, and individual model results departing by less than about 0.5°C. Because the interpretation of differences in model behaviour can be confounded by internal variability and forcing, some studies have attempted to identify and remove dominant factors such as El Niño-Southern Oscillation (ENSO) and the impacts of volcanic eruptions (e.g., Fyfe et al., 2010). Figure 9.8 shows the similar capability for EMICs to simulate the global-scale response to the 20th century forcings (Eby et al. 2013). These

results demonstrate a level of consistency between the EMICs with both the observations and the CMIP5 ensemble.

In summary, there is *very high confidence* that models reproduce the general features of the global-scale annual mean surface temperature increase over the historical period, including the more rapid warming in the second half of the 20th century, and the cooling immediately following large volcanic eruptions. The disagreement apparent over the most recent 10 to 15 years is discussed in detail in Box 9.2.

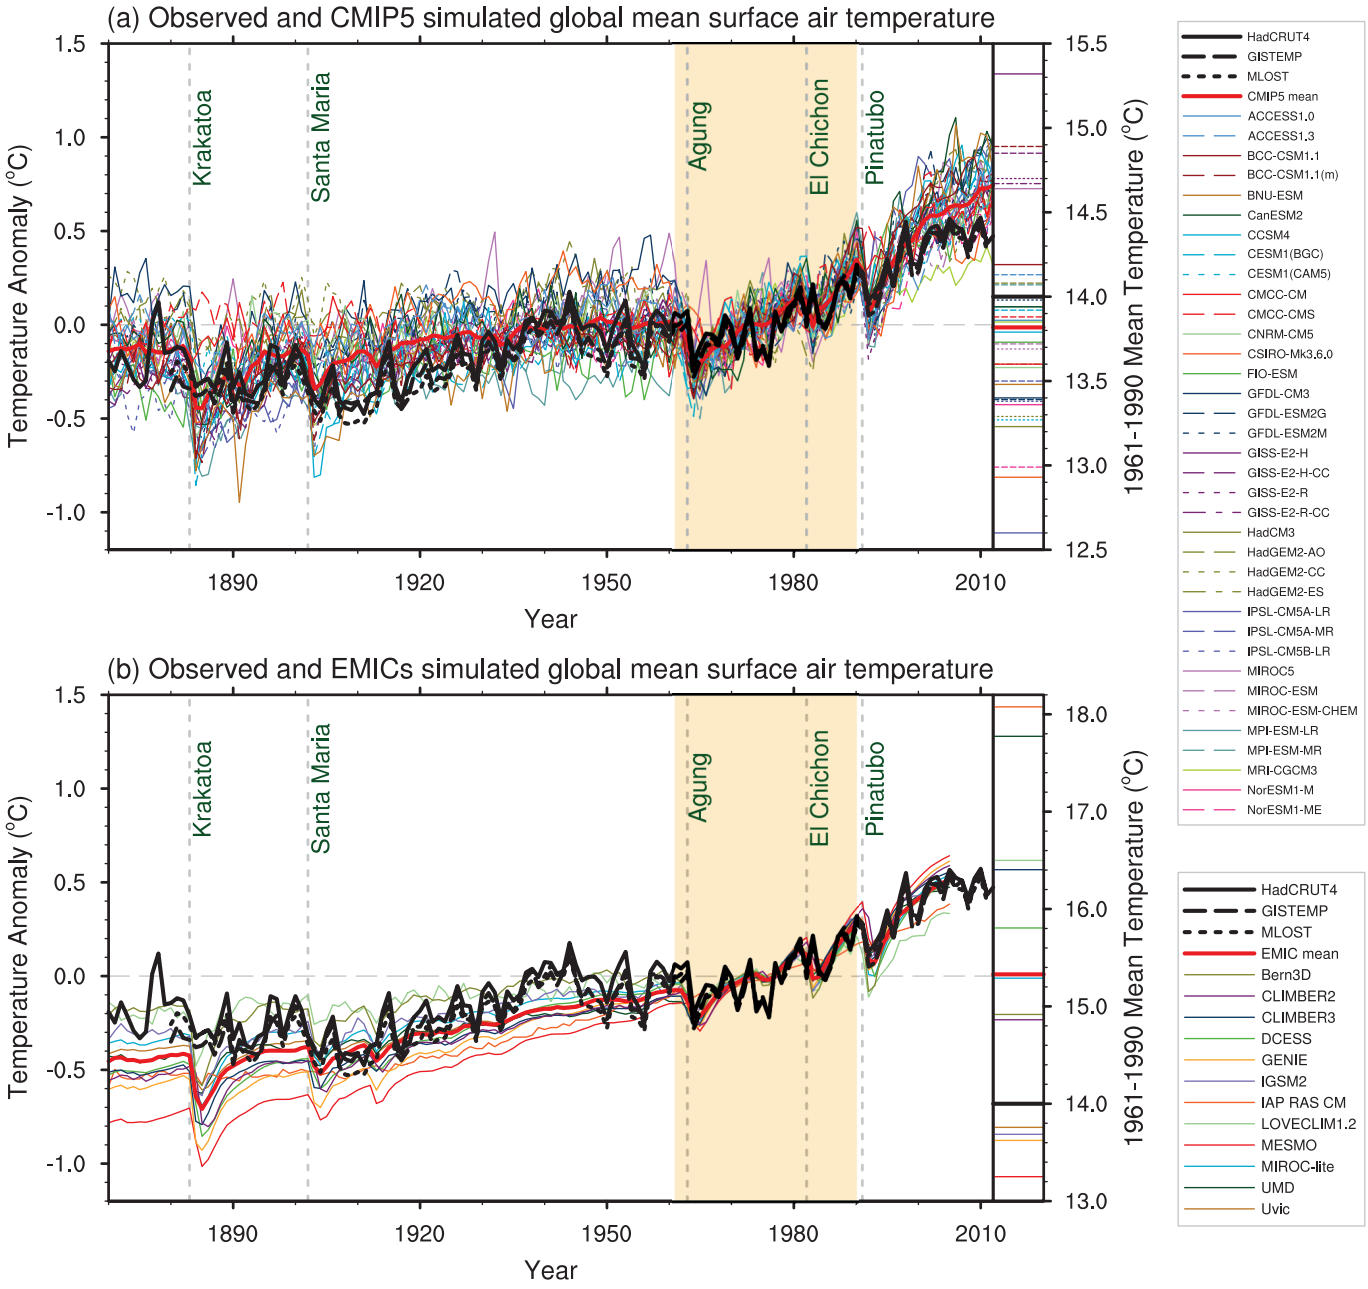

Figure 9.8 | Observed and simulated time series of the anomalies in annual and global mean surface temperature. All anomalies are differences from the 1961–1990 time-mean of each individual time series. The reference period 1961–1990 is indicated by yellow shading; vertical dashed grey lines represent times of major volcanic eruptions. (a) Single simulations for CMIP5 models (thin lines); multi-model mean (thick red line); different observations (thick black lines). Observational data (see Chapter 2) are Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4; Morice et al., 2012), Goddard Institute for Space Studies Surface Temperature Analysis (GISTEMP; Hansen et al., 2010) and Merged Land–Ocean Surface Temperature Analysis (MLOST; Vose et al., 2012) and are merged surface temperature (2 m height over land and surface temperature over the ocean). All model results have been sub-sampled using the HadCRUT4 observational data mask (see Chapter 10). Following the CMIP5 protocol (Taylor et al., 2012b), all simulations use specified historical forcings up to and including 2005 and use RCP4.5 after 2005 (see Figure 10.1 and note different reference period used there; results will differ slightly when using alternative RCP scenarios for the post-2005 period). (a) Inset: the global mean surface temperature for the reference period 1961–1990, for each individual model (colours), the CMIP5 multi-model mean (thick red), and the observations (thick black: Jones et al., 1999). (Bottom) Single simulations from available EMIC simulations (thin lines), from Eby et al. (2013). Observational data are the same as in (a). All EMIC simulations ended in 2005 and use the CMIP5 historical forcing scenario. (b) Inset: Same as in (a) but for the EMICs.

Box 9.2 | Climate Models and the Hiatus in Global Mean Surface Warming of the Past 15 Years

The observed global mean surface temperature (GMST) has shown a much smaller increasing linear trend over the past 15 years than over the past 30 to 60 years (Section 2.4.3, Figure 2.20, Table 2.7; Figure 9.8; Box 9.2 Figure 1a, c). Depending on the observational data set, the GMST trend over 1998–2012 is estimated to be around one-third to one-half of the trend over 1951–2012 (Section 2.4.3, Table 2.7; Box 9.2 Figure 1a, c). For example, in HadCRUT4 the trend is 0.04ºC per decade over 1998–2012, compared to 0.11ºC per decade over 1951–2012. The reduction in observed GMST trend is most marked in Northern Hemisphere winter (Section 2.4.3; Cohen et al., 2012). Even with this "hiatus" in GMST trend, the decade of the 2000s has been the warmest in the instrumental record of GMST (Section 2.4.3, Figure 2.19). Nevertheless, the occurrence of the hiatus in GMST trend during the past 15 years raises the two related questions of what has caused it and whether climate models are able to reproduce it.

Figure 9.8 demonstrates that 15-year-long hiatus periods are common in both the observed and CMIP5 historical GMST time series (see also Section 2.4.3, Figure 2.20; Easterling and Wehner, 2009; Liebmann et al., 2010). However, an analysis of the full suite of CMIP5 historical simulations (augmented for the period 2006–2012 by RCP4.5 simulations, Section 9.3.2) reveals that 111 out of 114 realizations show a GMST trend over 1998–2012 that is higher than the entire HadCRUT4 trend ensemble (Box 9.2 Figure 1a; CMIP5 ensemble mean trend is 0.21ºC per decade). This difference between simulated and observed trends could be caused by some combination of (a) internal climate variability, (b) missing or incorrect radiative forcing and (c) model response error. These potential sources of the difference, which are not mutually exclusive, are assessed below, as is the cause of the observed GMST trend hiatus.

Internal Climate Variability

Hiatus periods of 10 to 15 years can arise as a manifestation of internal decadal climate variability, which sometimes enhances and sometimes counteracts the long-term externally forced trend. Internal variability thus diminishes the relevance of trends over periods as short as 10 to 15 years for long-term climate change (Box 2.2, Section 2.4.3). Furthermore, the timing of internal decadal climate variability is not expected to be matched by the CMIP5 historical simulations, owing to the predictability horizon of at most 10 to 20 years (Section 11.2.2; CMIP5 historical simulations are typically started around nominally 1850 from a control run). However, climate models exhibit individual decades of GMST trend hiatus even during a prolonged phase of energy uptake of the climate system (e.g., Figure 9.8; Easterling and Wehner, 2009; Knight et al., 2009), in which case the energy budget would be balanced by increasing subsurface–ocean heat uptake (Meehl et al., 2011, 2013a; Guemas et al., 2013).

Owing to sampling limitations, it is uncertain whether an increase in the rate of subsurface–ocean heat uptake occurred during the past 15 years (Section 3.2.4). However, it is *very likely*[2] that the climate system, including the ocean below 700 m depth, has continued to accumulate energy over the period 1998–2010 (Section 3.2.4, Box 3.1). Consistent with this energy accumulation, global mean sea level has continued to rise during 1998–2012, at a rate only slightly and insignificantly lower than during 1993–2012 (Section 3.7). The consistency between observed heat-content and sea level changes yields *high confidence* in the assessment of continued ocean energy accumulation, which is in turn consistent with the positive radiative imbalance of the climate system (Section 8.5.1; Section 13.3, Box 13.1). By contrast, there is *limited evidence* that the hiatus in GMST trend has been accompanied by a slower rate of increase in ocean heat content over the depth range 0 to 700 m, when comparing the period 2003–2010 against 1971–2010. There is *low agreement* on this slowdown, since three of five analyses show a slowdown in the rate of increase while the other two show the increase continuing unabated (Section 3.2.3, Figure 3.2).

During the 15-year period beginning in 1998, the ensemble of HadCRUT4 GMST trends lies below almost all model-simulated trends (Box 9.2 Figure 1a), whereas during the 15-year period ending in 1998, it lies above 93 out of 114 modelled trends (Box 9.2 Figure 1b; HadCRUT4 ensemble-mean trend 0.26°C per decade, CMIP5 ensemble-mean trend 0.16°C per decade). Over the 62-year period 1951–2012, observed and CMIP5 ensemble-mean trends agree to within 0.02ºC per decade (Box 9.2 Figure 1c; CMIP5 ensemble-mean trend 0.13°C per decade). There is hence *very high confidence* that the CMIP5 models show long-term GMST trends consistent with observations, despite the disagreement over the most recent 15-year period. Due to internal climate variability, in any given 15-year period the observed GMST trend sometimes lies near one end of a model ensemble (Box 9.2, Figure 1a, b; Easterling and Wehner, 2009), an effect that is pronounced in Box 9.2, Figure 1a, b because GMST was influenced by a very strong El Niño event in 1998.

(continued on next page)

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

Box 9.2 (continued)

Unlike the CMIP5 historical simulations referred to above, some CMIP5 predictions were initialized from the observed climate state during the late 1990s and the early 21st century (Section 11.1, Box 11.1; Section 11.2). There is *medium evidence* that these initialized predictions show a GMST lower by about 0.05ºC to 0.1ºC compared to the historical (uninitialized) simulations and maintain this lower GMST during the first few years of the simulation (Section 11.2.3.4, Figure 11.3 top left; Doblas-Reyes et al., 2013; Guemas et al., 2013). In some initialized models this lower GMST occurs in part because they correctly simulate a shift, around 2000, from a positive to a negative phase of the Interdecadal Pacific Oscillation (IPO, Box 2.5; e.g., Meehl and Teng, 2012; Meehl et al., 2013a). However, the improvement of this phasing of the IPO through initialization is not universal across the CMIP5 predictions (cf. Section 11.2.3.4). Moreover, while part of the GMST reduction through initialization indeed results from initializing at the correct phase of internal variability, another part may result from correcting a model bias that was caused by incorrect past forcing or incorrect model response to past forcing, especially in the ocean. The relative magnitudes of these effects are at present unknown (Meehl and Teng, 2012); moreover, the quality of a forecasting system cannot be evaluated from a single prediction (here, a 10-year prediction within the period 1998–2012; Section 11.2.3). Overall, there is *medium confidence* that initialization leads to simulations of GMST during 1998–2012 that are more consistent with the observed trend hiatus than are the uninitialized CMIP5 historical simulations, and that the hiatus is in part a consequence of internal variability that is predictable on the multi-year time scale.

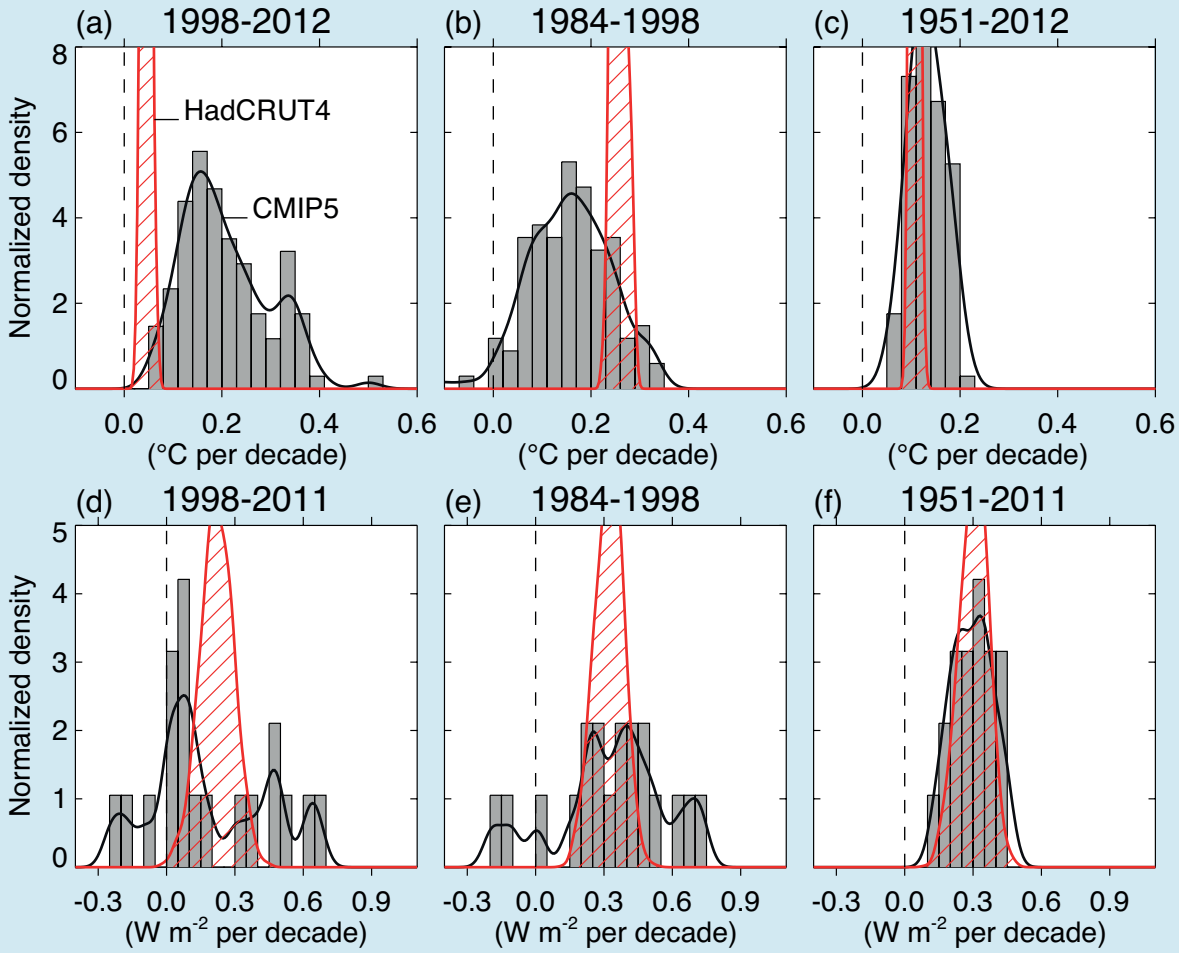
Radiative Forcing

On decadal to interdecadal time scales and under continually increasing effective radiative forcing (ERF), the forced component of the GMST trend responds to the ERF trend relatively rapidly and almost linearly (*medium confidence*, e.g., Gregory and Forster, 2008; Held et al., 2010; Forster et al., 2013). The expected forced-response GMST trend is related to the ERF trend by a factor that has been estimated for the 1% per year CO_2 increases in the CMIP5 ensemble as 2.0 [1.3 to 2.7] W m^{-2} $°C^{-1}$ (90% uncertainty range; Forster et al., 2013). Hence, an ERF trend can be approximately converted to a forced-response GMST trend, permitting an assessment of how much of the change in the GMST trends shown in Box 9.2 Figure 1 is due to a change in ERF trend.

The AR5 best-estimate ERF trend over 1998–2011 is 0.22 [0.10 to 0.34] W m^{-2} per decade (90% uncertainty range), which is substantially lower than the trend over 1984–1998 (0.32 [0.22 to 0.42] W m^{-2} per decade; note that there was a strong volcanic eruption in 1982) and the trend over 1951–2011 (0.31 [0.19 to 0.40] W m^{-2} per decade; Box 9.2, Figure 1d–f; numbers based on Section 8.5.2, Figure 8.18; the end year 2011 is chosen because data availability is more limited than for GMST). The resulting forced-response GMST trend would approximately be 0.12 [0.05 to 0.29] °C per decade, 0.19 [0.09 to 0.39] °C per decade, and 0.18 [0.08 to 0.37] °C per decade for the periods 1998–2011, 1984–1998 and 1951–2011, respectively (the uncertainty ranges assume that the range of the conversion factor to GMST trend and the range of ERF trend itself are independent). The AR5 best-estimate ERF forcing trend difference between 1998–2011 and 1951–2011 thus might explain about one-half (0.05°C per decade) of the observed GMST trend difference between these periods (0.06 to 0.08°C per decade, depending on observational data set).

The reduction in AR5 best-estimate ERF trend over 1998–2011 compared to both 1984–1998 and 1951–2011 is mostly due to decreasing trends in the natural forcings,–0.16 [–0.27 to –0.06] W m^{-2} per decade over 1998–2011 compared to 0.01 [–0.00 to 0.01] W m^{-2} per decade over 1951–2011 (Section 8.5.2, Figure 8.19). Solar forcing went from a relative maximum in 2000 to a relative minimum in 2009, with a peak-to-peak difference of around 0.15 W m^{-2} and a linear trend over 1998–2011 of around –0.10 W m^{-2} per decade (cf. Section 10.3.1, Box 10.2). Furthermore, a series of small volcanic eruptions has increased the observed stratospheric aerosol loading after 2000, leading to an additional negative ERF linear-trend contribution of around –0.06 W m^{-2} per decade over 1998–2011 (cf. Section 8.4.2.2, Section 8.5.2, Figure 8.19; Box 9.2 Figure 1d, f). By contrast, satellite-derived estimates of tropospheric aerosol optical depth (AOD) suggests little overall trend in global mean AOD over the last 10 years, implying little change in ERF due to aerosol-radiative interaction (*low confidence* because of *low confidence* in AOD trend itself, Section 2.2.3; Section 8.5.1; Murphy, 2013). Moreover, because there is only *low confidence* in estimates of ERF due to aerosol–cloud interaction (Section 8.5.1, Table 8.5), there is likewise *low confidence* in its trend over the last 15 years.

For the periods 1984–1998 and 1951–2011, the CMIP5 ensemble-mean ERF trend deviates from the AR5 best-estimate ERF trend by only 0.01 W m^{-2} per decade (Box 9.2 Figure 1e, f). After 1998, however, some contributions to a decreasing ERF trend are missing in the CMIP5 models, such as the increasing stratospheric aerosol loading after 2000 and the unusually low solar minimum in 2009. Nonetheless, over 1998–2011 the CMIP5 ensemble-mean ERF trend is lower than the AR5 best-estimate ERF trend by 0.03 W m^{-2} per decade (Box 9.2 Figure 1d). Furthermore, global mean AOD in the CMIP5 models shows little trend over 1998–2012, similar to the observations (Figure 9.29). Although the forcing uncertainties are substantial, there are no apparent incorrect or missing global mean forcings in the CMIP5 models over the last 15 years that could explain the model–observations difference during the warming hiatus.



(continued on next page)

Box 9.2 (continued)

Model Response Error

The discrepancy between simulated and observed GMST trends during 1998–2012 could be explained in part by a tendency for some CMIP5 models to simulate stronger warming in response to increases in greenhouse gas (GHG) concentration than is consistent with observations (Section 10.3.1.1.3, Figure 10.4). Averaged over the ensembles of models assessed in Section 10.3.1.1.3, the best-estimate GHG and other anthropogenic (OA) scaling factors are less than one (though not significantly so, Figure 10.4), indicating that the model-mean GHG and OA responses should be scaled down to best match observations. This finding provides evidence that some CMIP5 models show a larger response to GHGs and other anthropogenic factors (dominated by the effects of aerosols) than the real world (*medium confidence*). As a consequence, it is argued in Chapter 11 that near-term model projections of GMST increase should be scaled down by about 10% (Section 11.3.6.3). This downward scaling is, however, not sufficient to explain the model-mean overestimate of GMST trend over the hiatus period.

Another possible source of model error is the poor representation of water vapour in the upper atmosphere (Section 9.4.1.2). It has been suggested that a reduction in stratospheric water vapour after 2000 caused a reduction in downward longwave radiation and hence a surface-cooling contribution (Solomon et al., 2010), possibly missed by the models, However, this effect is assessed here to be small, because there was a recovery in stratospheric water vapour after 2005 (Section 2.2.2.1, Figure 2.5). (continued on next page)

Box 9.2, Figure 1 | (Top) Observed and simulated global mean surface temperature (GMST) trends in degrees Celsius per decade, over the periods 1998–2012 (a), 1984–1998 (b), and 1951–2012 (c). For the observations, 100 realizations of the Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4) ensemble are shown (red, hatched: Morice et al., 2012). The uncertainty displayed by the ensemble width is that of the statistical construction of the global average only, in contrast to the trend uncertainties quoted in Section 2.4.3, which include an estimate of internal climate variability. Here, by contrast, internal variability is characterized through the width of the model ensemble. For the models, all 114 available CMIP5 historical realizations are shown, extended after 2005 with the RCP4.5 scenario and through 2012 (grey, shaded: after Fyfe et al., 2010). (Bottom) Trends in effective radiative forcing (ERF, in W m^{-2} per decade) over the periods 1998–2011 (d), 1984–1998 (e), and 1951–2011 (f). The figure shows AR5 best-estimate ERF trends (red, hatched; Section 8.5.2, Figure 8.18) and CMIP5 ERF (grey, shaded: from Forster et al., 2013). Black lines are smoothed versions of the histograms. Each histogram is normalized so that its area sums up to one.

Box 9.2 (continued)

In summary, the observed recent warming hiatus, defined as the reduction in GMST trend during 1998–2012 as compared to the trend during 1951–2012, is attributable in roughly equal measure to a cooling contribution from internal variability and a reduced trend in external forcing (expert judgment, *medium confidence*). The forcing trend reduction is primarily due to a negative forcing trend from both volcanic eruptions and the downward phase of the solar cycle. However, there is *low confidence* in quantifying the role of forcing trend in causing the hiatus, because of uncertainty in the magnitude of the volcanic forcing trend and *low confidence* in the aerosol forcing trend.

Almost all CMIP5 historical simulations do not reproduce the observed recent warming hiatus. There is *medium confidence* that the GMST trend difference between models and observations during 1998–2012 is to a substantial degree caused by internal variability, with possible contributions from forcing error and some CMIP5 models overestimating the response to increasing GHG and other anthropogenic forcing. The CMIP5 model trend in ERF shows no apparent bias against the AR5 best estimate over 1998–2012. However, *confidence* in this assessment of CMIP5 ERF trend is *low*, primarily because of the uncertainties in model aerosol forcing and processes, which through spatial heterogeneity might well cause an undetected global mean ERF trend error even in the absence of a trend in the global mean aerosol loading.

The causes of both the observed GMST trend hiatus and of the model–observation GMST trend difference during 1998–2012 imply that, barring a major volcanic eruption, most 15-year GMST trends in the near-term future will be larger than during 1998–2012 (*high confidence*; see 11.3.6.3. for a full assessment of near-term projections of GMST). The reasons for this implication are fourfold: first, anthropogenic greenhouse-gas concentrations are expected to rise further in all RCP scenarios; second, anthropogenic aerosol concentration is expected to decline in all RCP scenarios, and so is the resulting cooling effect; third, the trend in solar forcing is expected to be larger over most near-term 15-year periods than over 1998–2012 (*medium confidence*), because 1998–2012 contained the full downward phase of the solar cycle; and fourth, it is *more likely than not* that internal climate variability in the near-term will enhance and not counteract the surface warming expected to arise from the increasing anthropogenic forcing.

9.4.1.4.2 Tropical tropospheric temperature trends

Most climate model simulations show a larger warming in the tropical troposphere than is found in observational data sets (e.g., McKitrick et al., 2010; Santer et al., 2013). There has been an extensive and sometimes controversial debate in the published literature as to whether this difference is statistically significant, once observational uncertainties and natural variability are taken into account (e.g., Douglass et al., 2008; Santer et al., 2008, 2013; Christy et al., 2010; McKitrick et al., 2010; Bengtsson and Hodges, 2011; Fu et al., 2011; McKitrick et al., 2011; Thorne et al., 2011). For the period 1979–2012, the various observational data sets find, in the tropical lower troposphere (LT), a linear warming trend ranging from 0.06°C to 0.13°C per decade (Section 2.4.4, Figure 2.27). In the tropical middle troposphere (MT), the linear warming trend ranges from 0.02°C to 0.12°C per decade (Section 2.4.4, Figure 2.27). Uncertainty in these trend values arises from different methodological choices made by the groups deriving satellite products (Mears et al., 2011) and radiosonde compilations (Thorne et al., 2011), and from fitting a linear trend to a time series containing substantial interannual and decadal variability (Box 2.2; Section 2.4.4; (Santer et al., 2008; McKitrick et al., 2010)). Although there have been substantial methodological debates about the calculation of trends and their uncertainty, a 95% confidence interval of around ±0.1°C per decade has been obtained consistently for both LT and MT (e.g., Section 2.4.4; McKitrick et al., 2010). In summary, despite unanimous agreement on the sign of the observed trends, there exists substantial disagreement between available estimates as to the rate of temperature changes in the tropical troposphere, and there is only *low confidence* in the rate of change and its vertical structure (Section 2.4.4).

For the 30-year period 1979–2009 (sometimes updated through 2010 or 2011), the CMIP3 models simulate a tropical warming trend ranging from 0.1°C to somewhat above 0.4°C per decade for both LT and MT (McKitrick et al., 2010), while the CMIP5 models simulate a tropical warming trend ranging from slightly below 0.15°C to somewhat above 0.4°C per decade for both LT and MT (Santer et al., 2013; see also Po-Chedley and Fu, 2012, who considered the period 1979–2005). Both model ensembles show trends that on average are higher than in the observational estimates, although both model ensembles overlap the observational ensemble. Because the differences between the various observational estimates are largely systematic and structural (Section 2.4.4; Mears et al., 2011), the uncertainty in the observed trends cannot be reduced by averaging the observations as if the differences between the data sets were purely random. Likewise, to properly represent internal climate variability, the full model ensemble spread must be used in a comparison against the observations (e.g., Box 9.2; Section 11.2.3.2; Raftery et al., 2005; Wilks, 2006; Jolliffe and Stephenson, 2011). The very high significance levels of model–observation discrepancies in LT and MT trends that were obtained in some studies (e.g., Douglass et al., 2008; McKitrick et al., 2010) thus arose to a substantial degree from using the standard error of the model ensemble mean as a measure of uncertainty, instead of the ensemble standard deviation or some other appropriate measure for uncertainty arising from internal climate

variability (e.g., Box 9.2; Section 11.2.3.2; Raftery et al., 2005; Wilks, 2006; Jolliffe and Stephenson, 2011). Nevertheless, almost all model ensemble members show a warming trend in both LT and MT larger than observational estimates (McKitrick et al., 2010; Po-Chedley and Fu, 2012; Santer et al., 2013).

The CMIP3 models show a 1979–2010 tropical SST trend of 0.19°C per decade in the multi-model mean, significantly larger than the various observational trend estimates ranging from 0.10°C to 0.14°C per decade (including the 95% confidence interval; Fu et al., 2011). As a consequence, simulated tropospheric temperature trends are also too large because models attempt to maintain static stability. By contrast, atmospheric models that are forced with the observed SST are in better agreement with observations, as was found in the CMIP3 model ECHAM5 (Bengtsson and Hodges, 2011) and the CMIP5 atmosphere-only runs. In the latter, the LT trend range for the period 1981–2008 is 0.13 to 0.19ºC per decade—less than in the CMIP5 coupled models, but still an overestimate (Po-Chedley and Fu, 2012). The influence of SST trend errors on the analysis can be reduced by considering trends in tropospheric static stability, measured by the amplification of MT trends against LT trends; another approach is to consider the amplification of tropospheric trends against SST trends. The results of such analyses strongly depend on the time scale considered. Month-to-month variations are consistent between observations and models concerning amplification aloft against SST variations (Santer et al., 2005) and concerning amplification of MT against LT variations (Po-Chedley and Fu, 2012). By contrast, the 30-year trend in tropical static stability has been found to be larger than in the satellite observations for almost all ensemble members in both CMIP3 (Fu et al., 2011) and CMIP5 (Po-Chedley and Fu, 2012). However, if the radiosonde compilations are used for the comparison, the trends in static stability in the CMIP3 models agree much better with the observations, and inconsistency cannot be diagnosed unambiguously (Seidel et al., 2012) . What caused the remaining trend overestimate in static stability is not clear but has been argued recently to result from an upward propagation of bias in the model climatology (O'Gorman and Singh, 2013).

In summary, most, though not all, CMIP3 and CMIP5 models overestimate the observed warming trend in the tropical troposphere during the satellite period 1979–2012. Roughly one-half to two-thirds of this difference from the observed trend is due to an overestimate of the SST trend, which is propagated upward because models attempt to maintain static stability. There is *low confidence* in these assessments, however, due to the *low confidence* in observed tropical tropospheric trend rates and vertical structure (Section 2.4.4).

9.4.1.4.3 Extratropical circulation

The AR4 concluded that models, when forced with observed SSTs, are capable of producing the spatial distribution of storm tracks, but generally show deficiencies in the numbers and depth of cyclones and the exact locations of the storm tracks. The ability to represent extratropical cyclones in climate models has been improving, partly due to increases in horizontal resolution.

Storm track biases over the North Atlantic have decreased in CMIP5 models compared to CMIP3 (Zappa et al., 2013) although models still produce too zonal a storm track in this region and most models underestimate cyclone intensity (Colle et al., 2013; Zappa et al., 2013). Chang et al. (2012) also find the storm tracks in the CMIP5 models to be too weak and too equatorwards in their position, similar to the CMIP3 models. The performance of the CMIP5 models in representing North Atlantic cyclones was found to be strongly dependent on model resolution (Colle et al., 2013). Studies based on individual models typically find that models capture the general characteristics of storm tracks and extratropical cyclones (Ulbrich et al., 2008; Catto et al., 2010) and their associated fronts (Catto et al., 2013) and show improvements over earlier model versions (Loptien et al., 2008). However, some models have deficiencies in capturing the location of storm tracks (Greeves et al., 2007; Catto et al., 2011), in part owing to problems related to the location of warm waters such as the Gulf Stream and Kuroshio Current (Greeves et al., 2007; Keeley et al., 2012). This is an important issue because future projections of storm tracks are sensitive to changes in SSTs (Catto et al., 2011; Laine et al., 2011; McDonald, 2011; Woollings et al., 2012). Some studies find that storm track and cyclone biases are strongly related to atmospheric processes and parameterizations (Bauer et al., 2008a; Boer and Lambert, 2008; Zappa et al., 2013). Representation of the Mediterranean storm track has been shown to be particularly dependent on model resolution (Pinto et al., 2006; Raible et al., 2007; Bengtsson et al., 2009; Ulbrich et al., 2009), as is the representation of storm intensity and associated extremes in this area (Champion et al., 2011). Most studies have focussed on NH storm tracks. However, recently two CMIP3 models were found to differ significantly in their simulation of extratropical cyclones affecting Australia (Dowdy et al., 2013) and only about a third of the CMIP3 models were able to capture the observed changes and trends in Southern Hemisphere (SH) baroclinicity responsible for a reduction in the growth rate of the leading winter storm track modes (Frederiksen et al., 2011). There is still a lack of information on SH storm track evaluation for the CMIP5 models.

9.4.1.4.4 Tropical circulation

Earlier assessments of a weakening Walker circulation (Vecchi et al., 2006; Vecchi and Soden, 2007; DiNezio et al., 2009) from models and reanalyses (Yu and Zwiers, 2010) have been tempered by subsequent evidence that tropical Pacific Trade winds may have strengthened since the early 1990s (e.g., Merrifield and Maltrud, 2011). Models suggest that the width of the Hadley cell should increase (Frierson et al., 2007; Lu et al., 2007), and there are indications that this has been observed over the past 25 years (Seidel et al., 2008) but at an apparent rate (2 to 5 degrees of latitude since 1979) that is faster than in the CMIP3 models (Johanson and Fu, 2009).

The tendency in a warming climate for wet areas to receive more precipitation and subtropical dry areas to receive less, often termed the 'rich-get richer' mechanism (Chou et al., 2006; Held and Soden, 2006) is simulated in CMIP3 models (Chou and Tu, 2008), and observational support for this is found from ocean salinity observations (Durack et al., 2012) and precipitation gauge data over land (Zhang et al., 2007). There is *medium confidence* that models are correct in simulating precipitation increases in wet areas and decreases in dry areas on broad spatial scales in a warming climate based on agreement among models and some evidence that this has been detected in observed trends (see Section 2.5.1).

Several recent studies have examined the co-variability of tropical climate variables as a further means of evaluating climate models. Specifically, there are observed relationships between lower tropospheric temperature and total column precipitable water (Mears et al., 2007), and between surface temperature and relative humidity (Willett et al., 2010). Figure 9.9 (updated from Mears et al., 2007) shows the relationship between 25-year (1988–2012) linear trends in tropical precipitable water and lower tropospheric temperature for individual historical simulations (extended by appending RCP8.5 simulations after 2005, see Santer et al., 2013). As described by Mears et al. (2007), the ratio between changes in these two quantities is fairly tightly constrained in the model simulations and similar across a range of time scales, indicating that relative humidity is close to invariant in each model. In the updated figure, the Remote Sensing System (RSS) observations are in fairly good agreement with model expectations, and the University of Alabama in Huntsville (UAH) observations less so. The points associated with two of the reanalyses are also relatively far from the line, consistent with long-term changes in relative humidity. It is not known whether these discrepancies are due to remaining inhomogeneity in the observational data and/or reanalysis results, or due to problems with the climate simulations. All of the observational and reanalysis points lie at the lower end of the model distribution, consistent with the findings of (Santer et al., 2013).

9.4.1.4.5 Ozone and lower stratospheric temperature trends

Stratospheric ozone has been subject to a major perturbation since the late 1970s due to anthropogenic emissions of ozone-depleting substances (see also Section 2.2.2.2 and Figure 2.6). Since the AR4, there is increasing evidence that the ozone hole has led to a poleward shift and strengthening of the SH mid-latitude tropospheric jet during summer (Perlwitz et al., 2008; Son et al., 2008, 2010; SPARC-CCMVal, 2010; McLandress et al., 2011; Polvani et al., 2011; WMO, 2011; Swart and Fyfe, 2012b). These trends are well captured in both chemistry–climate models (CCMs) with interactive stratospheric chemistry and in CMIP3 models with prescribed time-varying ozone (Son et al., 2010; SPARC-CCMVal, 2010). However, around half of the CMIP3 models prescribe ozone as a fixed climatological value, and so these models are not able to simulate trends in surface climate attributable to changing stratospheric ozone amount (Karpechko et al., 2008; Son et al., 2008, 2010; Fogt et al., 2009). For CMIP5, a new time-varying ozone data set (Cionni et al., 2011) was developed and prescribed in the majority of models without interactive chemistry. This zonal mean data set is based on observations by Randel and Wu (2007) and CCM projections in the future (SPARC-CCMVal, 2010). Further, nine of the CMIP5 models include interactive chemistry and so compute their own ozone evolution. As a result, all CMIP5 models consider stratospheric ozone depletion and capture associated effects on SH surface climate, a significant advance over CMIP3. Figure 9.10 shows the global annual mean and Antarctic October mean of total column ozone in the CMIP5 models. The simulated trends in total column ozone are in medium agreement with observations, noting that some models that calculate ozone interactively show significant deviations from observation (Eyring et al., 2013). The multi-model mean agrees well with observations, and there is *robust evidence* that this constitutes a significant improvement over CMIP3, where around half of the models did not include stratospheric

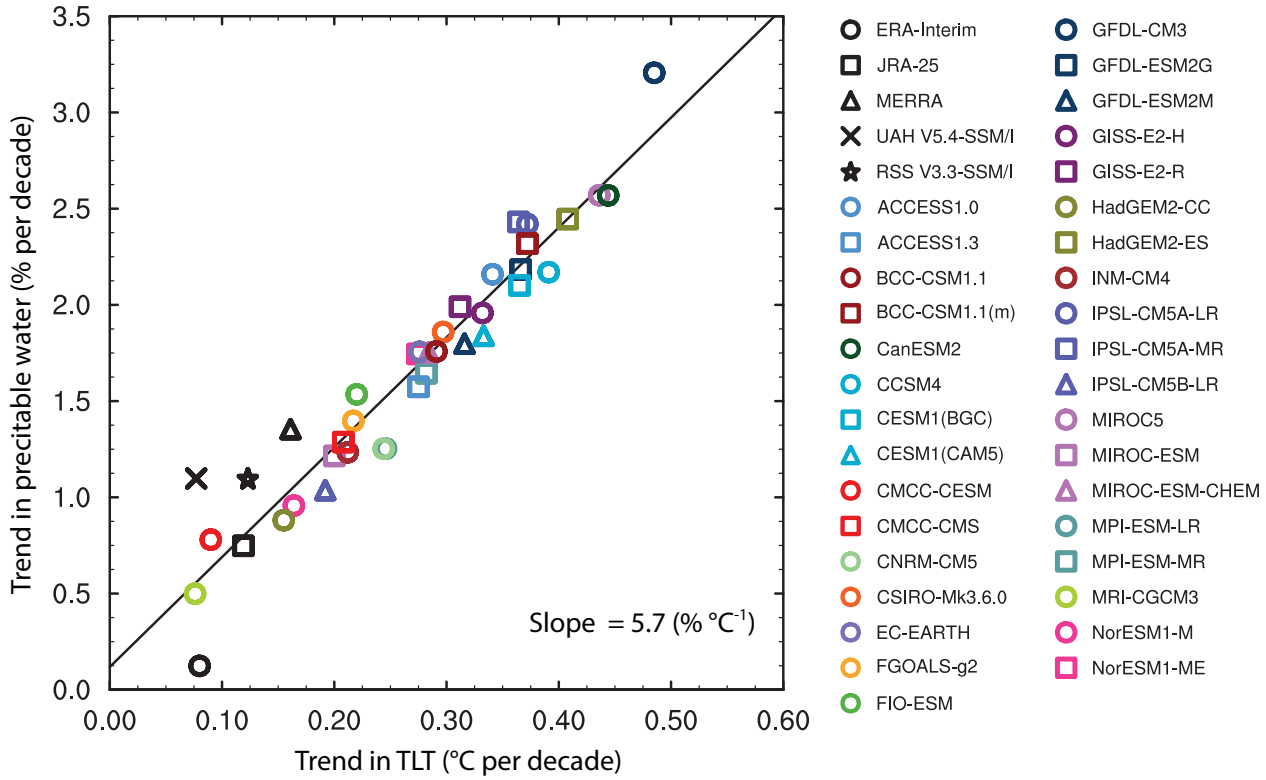


Figure 9.9 | Scatter plot of decadal trends in tropical (20°S to 20°N) precipitable water as a function of trends in lower tropospheric temperature (TLT) over the world's oceans. Coloured symbols are from CMIP5 models; black symbols are from satellite observations or from reanalysis output. Trends are calculated over the 1988–2012 period, so CMIP5 historical runs, which typically end in December 2005, were extended using RCP8.5 simulations initialized using these historical runs. Figure updated from Mears et al. (2007).

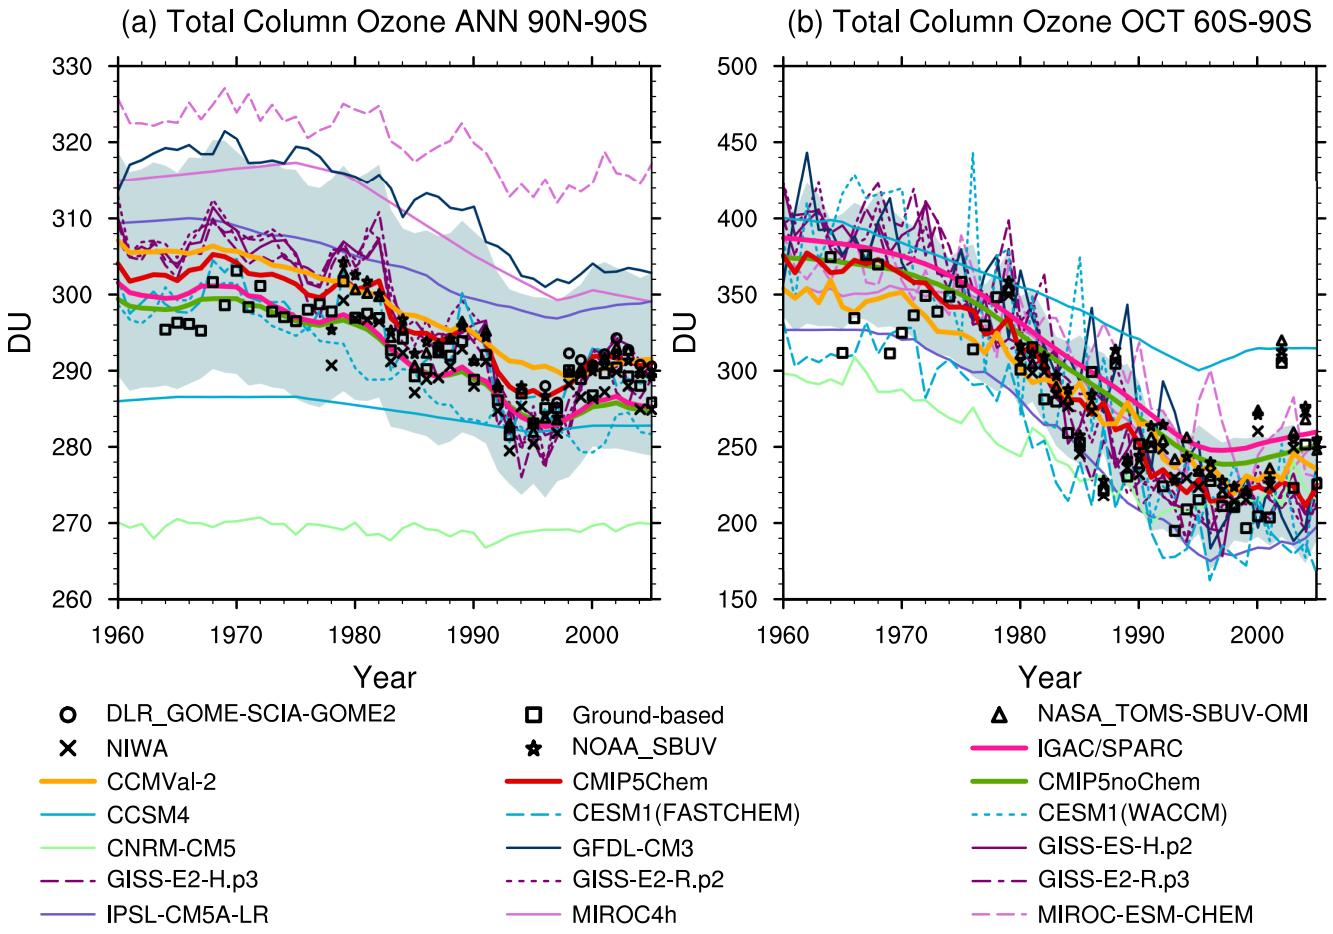

Figure 9.10 | Time series of area-weighted total column ozone from 1960 to 2005 for (a) annual and global mean (90°S to 90°N) and (b) Antarctic October mean (60°S to 90°S). Individual CMIP5 models with interactive or semi-interactive chemistry are shown in thin coloured lines, their multi-model mean (CMIP5Chem) in thick red and their standard deviation as the blue shaded area. Further shown are the multi-model mean of the CMIP5 models that prescribe ozone (CMIP5noChem, thick green), the International Global Atmospheric Chemistry/Stratospheric Processes and their Role in Climate (IGAC/SPARC) ozone database (thick pink), the Chemistry Climate Model Validation-2 (CCMVal-2) multi-model mean (thick orange), and observations from five different sources (black symbols). These sources include ground-based measurements (updated from Fioletov et al., 2002), National Aeronautics and Space Administration (NASA) Total Ozone Mapping Spectrometer/Ozone Monitoring Instrument/Solar Backscatter Ultraviolet(/2) (TOMS/OMI/SBUV(/2)) merged satellite data (Stolarski and Frith, 2006), the National Institute of Water and Atmospheric Research (NIWA) combined total column ozone database (Bodeker et al., 2005), Solar Backscatter Ultraviolet (SBUV, SBUV/2) retrievals (updated from Miller et al. 2002), and Deutsches Zentrum für Luft- und Raumfahrt/ Global Ozone Monitoring Experiment/ SCanning Imaging Absorption spectrometer for atmospheric chartography /GOME-2 (DLR GOME/SCIA/GOME-2; Loyola et al., 2009; Loyola and Coldewey-Egbers, 2012). Note that the IGAC/SPARC database over Antarctica (and thus the majority of the CMIP5noChem models) is based on ozonesonde measurements at the vortex edge (69°S) and as a result underestimates Antarctic ozone depletion compared to the observations shown. Ozone depletion was more pronounced after 1960 as equivalent stratospheric chlorine values steadily increased throughout the stratosphere. (Adapted from Figure 2 of Eyring et al., 2013.)

ozone trends. Correspondingly, there is *high confidence* that the representation of associated effects on high-latitude surface climate and lower stratospheric cooling trends has improved compared to CMIP3.

Lower stratospheric temperature change is affected by ozone, and since 1958 the change is characterized by a long-term global cooling trend interrupted by three 2-year warming episodes following large volcanic eruptions (Figure 2.24). During the satellite era (since 1979) the cooling occurred mainly in two step-like transitions in the aftermath of the El Chichón eruption in 1982 and the Mt Pinatubo eruption in 1991, with each cooling transition followed by a period of relatively steady temperatures (Randel et al., 2009; Seidel et al., 2011). This specific evolution of global lower stratosphere temperatures since 1979 is well captured in the CMIP5 models when forced with both natural and anthropogenic climate forcings, although the models tend to underestimate the long-term cooling trend (Charlton-Perez et al., 2012; Eyring et al., 2013; Santer et al., 2013) (see Chapter 10).

Tropospheric ozone is an important GHG and as such needs to be well represented in climate simulations. In the historical period it has increased due to increases in ozone precursor emissions from anthropogenic activities (see Chapters 2 and 8). Since the AR4, a new emission data set has been developed (Lamarque et al., 2010), which has led to some differences in tropospheric ozone burden compared to previous studies, mainly due to biomass burning emissions (Lamarque et al., 2010; Cionni et al., 2011; Young et al., 2013). Climatological mean tropospheric ozone in the CMIP5 simulations generally agrees well with satellite observations and ozonesondes, although as in the stratosphere, biases exist for individual models (Eyring et al., 2013; Young et al., 2013) (see also Chapter 8).

9.4.1.5 Model Simulations of the Last Glacial Maximum and the Mid-Holocene

Simulations of past climate can be used to test a model's response to forcings larger than those of the 20th century (see Chapter 5), and the CMIP5 protocol includes palaeoclimate simulations referred to as PMIP3 (Paleoclimate Model Intercomparison Project, version 3) (Taylor et al., 2012b). Specifically, the Last Glacial Maximum (LGM, 21000 years BP) allows testing of the modelled climate response to the presence of a large ice sheet in the NH and to lower concentrations of radiatively active trace gases, whereas the mid-Holocene (MH, 6000 years BP) tests the response to changes in seasonality of insolation in the NH (see Chapter 5). For these periods, palaeoclimate reconstructions allow quantitative model assessment (Braconnot et al., 2012). In addition the CMIP5/PMIP3 simulations can compared to previous palaeoclimate intercomparisons (Joussaume and Taylor, 1995; Braconnot et al., 2007c).

Figure 9.11 compares model results to palaeoclimate reconstructions for both LGM (left) and MH (right). For most models the simulated LGM cooling is within the range of the climate reconstructions (Braconnot et al., 2007c; Izumi et al., 2013), however Hargreaves et al. (2011) find a global mean model warm bias over the ocean of about 1°C for this period (Hargreaves et al., 2011). LGM simulations tend to overestimate tropical cooling and underestimate mid-latitude cooling (Kageyama et al., 2006; Otto-Bliesner et al., 2009). They thus underestimate polar amplification which is a feature also found for the mid-Holocene (Masson-Delmotte et al., 2006; Zhang et al., 2010a) and other climatic con-

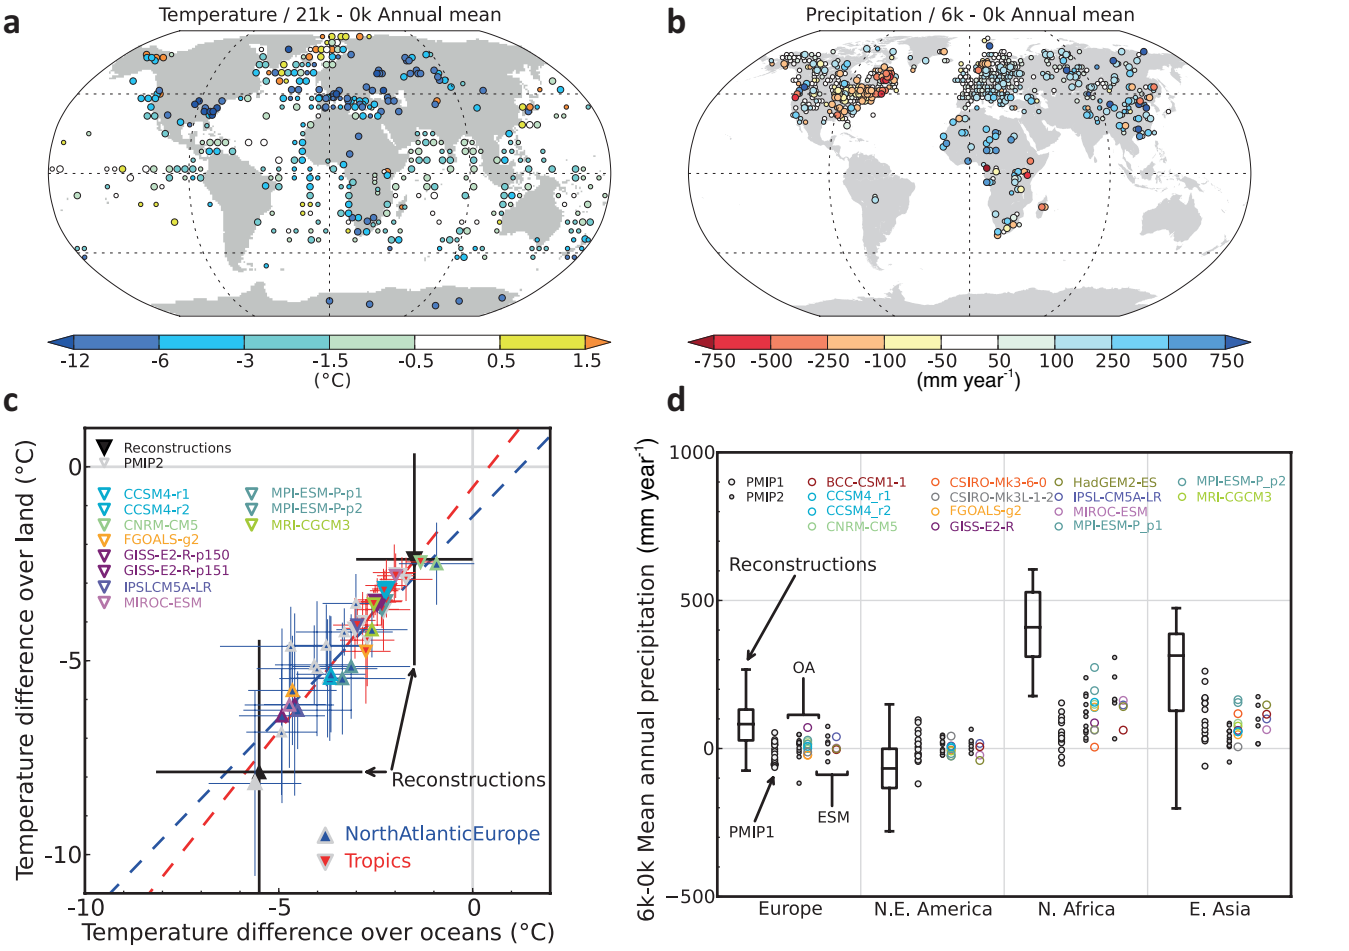

Figure 9.11 | Reconstructed and simulated conditions for the Last Glacial Maximum (LGM, 21,000 years BP, left) and the mid-Holocene (MH, 6000 years BP, right). (a) LGM change in annual mean surface temperature (°C) over land as shown by palaeo-environmental climate reconstructions from pollen, macrofossils, and ice cores (Bartlein et al., 2010; Braconnot et al., 2012), and in annual mean sea surface temperature (°C) over the ocean from different type of marine records (Waelbroeck et al., 2009). (b) MH change in annual mean precipitation (mm yr^{-1}) over land (Bartlein et al., 2010). In (a) and (b), the size of the dots is proportional to the uncertainties at the different sites as provided in the reconstructions. (c) Annual mean temperature changes over land against changes over the ocean, in the tropics (downward triangles) and over the North Atlantic and Europe (upward triangles). The mean and range of the reconstructions are shown in black, the Paleoclimate Modelling Intercomparison Project version 2 (PMIP2) simulations as grey triangles, and the CMIP5/PMIP3 simulations as coloured triangles. The 5 to 95% model ranges are in red for the tropics and in blue for the North Atlantic/Europe. (d) Changes in annual mean precipitation in different data-rich regions. Box plots for reconstructions provide the range of reconstructed values for the region. For models, the individual model average over the region is plotted for PMIP2 (small grey circle) and CMIP5/PMIP3 simulations (coloured circles). Note that in PMIP2, 'ESM' indicates that vegetation is computed using a dynamical vegetation model, whereas in CMIP5/PMIP3 it indicates that models have an interactive carbon cycle with different complexity in dynamical vegetation (see Table 9.A.1). The limits of the boxes are as follows: Western Europe (40°N to 50°N, 10°W to 30°E); northeast America (35°N to 60°N, 95°W to 60°W); North Africa (10°N to 25°N, 20°W to 30°W), and East Asia (25°N to 40°N, 75°E to 105°E). (Adapted from Braconnot et al., 2012.)

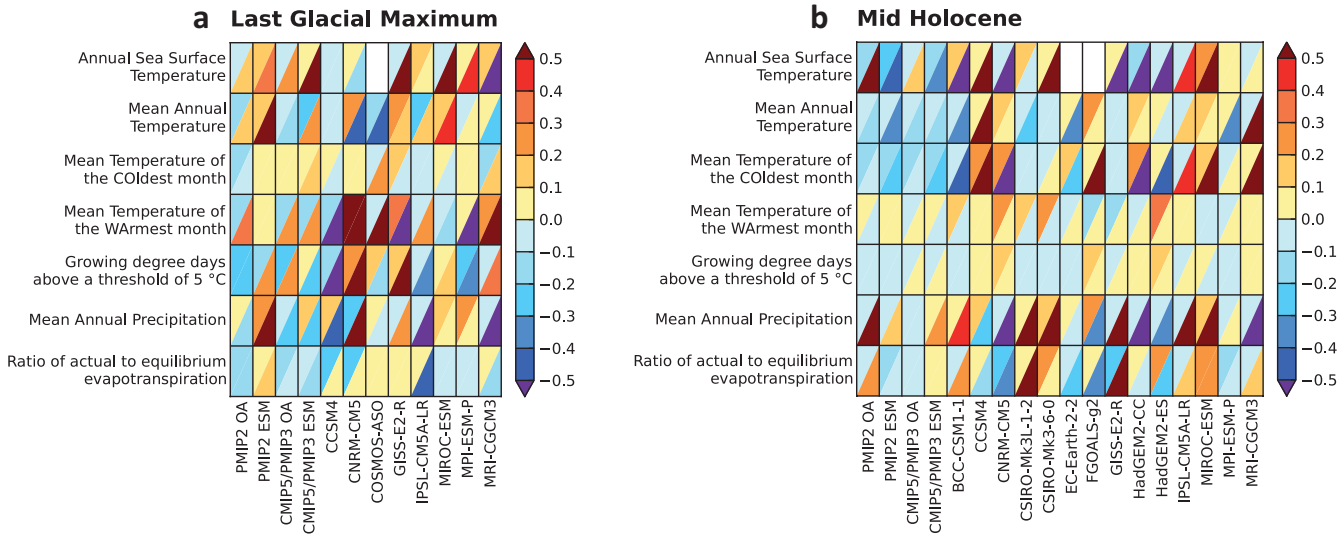

Figure 9.12 | Relative model performance for the Last Glacial Maximum (LGM, about 21,000 yr BP) and the mid-Holocene (MH, about 6000 yr BP) for seven bioclimatic variables: annual mean sea surface temperature, mean annual temperature (over land), mean temperature of the coldest month, mean temperature of the warmest month, growing degree days above a threshold of 5°C, and ratio of actual to equilibrium evapotranspiration. Model output is compared to the Bartlein et al. (2010) data set over land, including ice core data over Greenland and Antarctica (Braconnot et al., 2012) and the Margo data set (Waelbroeck et al., 2009) over the ocean. The CMIP5/Paleoclimate Modelling Intercomparison Project version 3 (PMIP3) ensemble of Ocean–Atmosphere (OA) and Earth System Model (ESM) simulations are compared to the respective PMIP2 ensembles in the first four columns of each panel. A diagonal divides each cell in two parts to show in the upper triangle a measure of the distance between model and data, taking into account the uncertainties in the palaeoclimate reconstructions (Guiot et al., 1999), and in the lower triangle the normalized mean-square error (NMSE) that indicates how well the spatial pattern is represented. In this graph all the values have been normalized following (Gleckler et al., 2008) using the median of the CMIP5/PMIP3 ensemble. The colour scale is such that blue colours mean that the result is better than the median CMIP5 model and red means that it is worse.

texts (Masson-Delmotte et al., 2010). Part of this can be attributed to uncertainties in the representation of sea ice and vegetation feedbacks that have been shown to amplify the response at the LGM and the MH in these latitudes (Braconnot et al., 2007b; Otto et al., 2009; O'ishi and Abe-Ouchi, 2011). Biases in the representation of the coupling between vegetation and soil moisture are also responsible for excessive continental drying at the LGM (Wohlfahrt et al., 2008) and uncertainties in vegetation feedback in monsoon regions (Wang et al., 2008; Dallmeyer et al., 2010). Nevertheless, the ratio between the simulated change in temperature over land and over the ocean (Figure 9.11c) is rather similar in different models, resulting mainly from simulation of the hydrological cycle over land and ocean (Sutton et al., 2007; Laine et al., 2009). At a regional scale, models tend to underestimate the changes in the north-south temperature gradient over Europe both at the LGM (Ramstein et al., 2007) and at the mid-Holocene (Brewer et al., 2007; Davis and Brewer, 2009).

The large-scale pattern of precipitation change during the MH (Figure 9.11d) is reproduced, but models tend to underestimate the magnitude of precipitation change in most regions. In the SH (not shown in the figure), the simulated change in atmospheric circulation is consistent with precipitation records in Patagonia and New Zealand, even though the differences between model results are large and the reconstructions have large uncertainties (Rojas et al., 2009; Rojas and Moreno, 2011).

A wider range of model performance metrics is provided in Figure 9.12 (Guiot et al., 1999; Brewer et al., 2007; Annan and Hargreaves, 2011; Izumi et al., 2013). Results for the MH are less reliable than for the LGM, because the forcing is weaker and involves smaller scale responses over the continent (Hargreaves et al., 2013). As is the case for the simulations of present day climate, there is only modest improvement between the results of the more recent models (CMIP5/PMIP3) and those of earlier model versions (PMIP2) despite higher resolution and sophistication.

9.4.2 Ocean

Accurate simulation of the ocean in climate models is essential for the correct estimation of transient ocean heat uptake and transient climate response, ocean CO_2 uptake, sea level rise, and coupled climate modes such as ENSO. In this section model performance is assessed for the mean state of ocean properties, surface fluxes and their impact on the simulation of ocean heat content and sea level, and aspects of importance for climate variability. Simulations of both the recent and more distant past are evaluated against available data. Following Chapter 3, ocean reanalyses are not used for model evaluation as many of their properties depend on the model used to build the reanalysis.

9.4.2.1 Simulation of Mean Temperature and Salinity Structure

Potential temperature and salinity are the main ocean state variables and their zonal distribution offers an evaluation of climate models in different parts of the ocean (upper ocean, thermocline, deep ocean). Over most latitudes, at depths ranging from 200 m to 2000 m, the CMIP5 multi-model mean zonally averaged ocean temperature is too warm (Figure 9.13a), albeit with a cooler deep ocean. Similar biases were evident in the CMIP3 multi-model mean. Above 200 m, however,

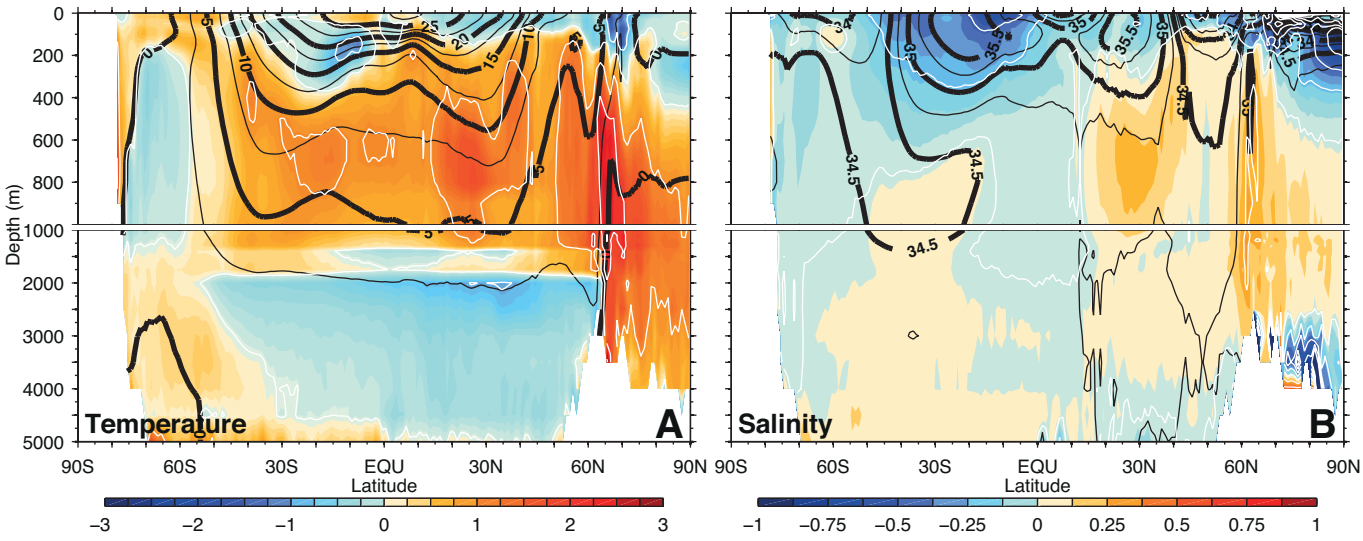

Figure 9.13 | (a) Potential temperature (oC) and (b) salinity (PSS-78); shown in colour are the time-mean differences between the CMIP5 ensemble mean and observations, zonally averaged for the global ocean (excluding marginal and regional seas). The observed climatological values are sourced from the World Ocean Atlas 2009 (WOA09; Prepared by the Ocean Climate Laboratory, National Oceanographic Data Center, Silver Spring, MD, USA), and are shown as labelled black contours. White contours show regions in (a) where potential temperature differences exceed positive or negative 1, 2 or 3°C, and in (b) where salinity differences exceed positive or negative 0.25, 0.5, 0.75 or 1 (PSS-78). The simulated annual mean climatologies are obtained for 1975 to 2005 from available historical simulations, whereas WOA09 synthesizes observed data from 1874 to 2008 in calculations of the annual mean; however, the median time for gridded observations most closely resembles the 1980–2010 period (Durack and Wijffels, 2012). Multiple realizations from individual models are first averaged to form a single-model climatology, before the construction of the multi-model ensemble mean. A total of 43 available CMIP5 models have contributed to the temperature panel (a) and 41 models to the salinity panel (b).

the CMIP5 (and CMIP3) multi-model mean is too cold, with maximum cold bias (more than 1°C) near the surface at mid-latitudes of the NH and near 200 m at 15°S. Zonal salinity errors (Figure 9.13b) exhibit a different pattern from those of the potential temperature indicating that most do not occur via density compensation. Some near surface structures in the tropics and in the northern mid-latitude are indicative of density compensation and are presumably due to surface fluxes errors. At intermediate depths, errors in water mass formation translate into errors in both salinity and potential temperature.

In the AR4 it was noted that the largest errors in SST in CMIP3 were found in mid and high latitudes. While this is still the case in CMIP5, there is marginal improvement with fewer individual models exhibiting serious bias—the inter-model zonal mean SST error standard deviation is significantly reduced at all latitudes north of 40°S—even though the multi-model mean is only slightly improved (Figure 9.14a, c). Near the equator, the cold tongue error in the Pacific (see Section 9.4.2.5.1) is reduced by 30% in CMIP5; the Atlantic still exhibits serious errors and the Indian is still well simulated (Figure 9.14b,d). In the Tropics, Li and Xie (2012) have shown that SST errors could be classified into those exhibiting broad meridional structures that are due to cloud errors, and those associated with Pacific and Atlantic cold tongue errors that are due to thermocline depth errors.

Sea surface salinity (SSS) is more challenging to observe, even though the last decade has seen substantial improvements in the development of global salinity observations, such as those from the Array for Real-time Geostrophic Oceanography (ARGO) network (see Chapter 3). Whereas SST is strongly constrained by air–sea interactions, the sources of SSS variations (surface forcing via evaporation minus precipitation, sea ice formation/melt and river runoff) are only loosely related to the SSS itself, allowing errors to develop unchecked in coupled models. An analysis of CMIP3 models showed that, whereas the historical trend in global mean SSS is well captured by the models, regional SSS biases are as high as ±2.5 psu (Terray et al., 2012). Comparisons of modelled versus observed estimates of evaporation minus precipitation suggest that model biases in surface freshwater flux play a role in some regions (e.g., double Intertropical Convergence Zone (ITCZ) in the East Pacific; Lin, 2007) or over the Indian ocean (Pokhrel et al., 2012).

The performance of coupled climate models in simulating hydrographic structure and variability were assessed in two important regions, the Labrador and Irminger Seas and the Southern Ocean (de Jong et al., 2009) and (Sloyan and Kamenkovich, 2007). Eight CMIP3 models produce simulations of the intermediate and deep layers in the Labrador and Irminger Seas that are generally too warm and saline, with biases up to 0.7 psu and 2.9°C. The biases arise because the convective regime is restricted to the upper 500 m; thus, intermediate water that in reality is formed by convection is, in the models, partly replaced by warmer water from the south. In the Southern Ocean, Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW), two water masses indicating very efficient ocean ventilation, are found to be well simulated in some CMIP3 and CMIP5 models but not in others, some having a significant fresh bias (Sloyan and Kamenkovich, 2007; Salle et al., 2013). McClean and Carman (2011) found biases in the properties of the North Atlantic mode waters and their formation rates in the CMIP3 models. Errors in Subtropical Mode Water (STMW) formation rate and volume produce a turnover time of 1 to 2 years, approximately half of that observed. Bottom water properties assessment in CMIP5 shows that about half of the models create dense water on

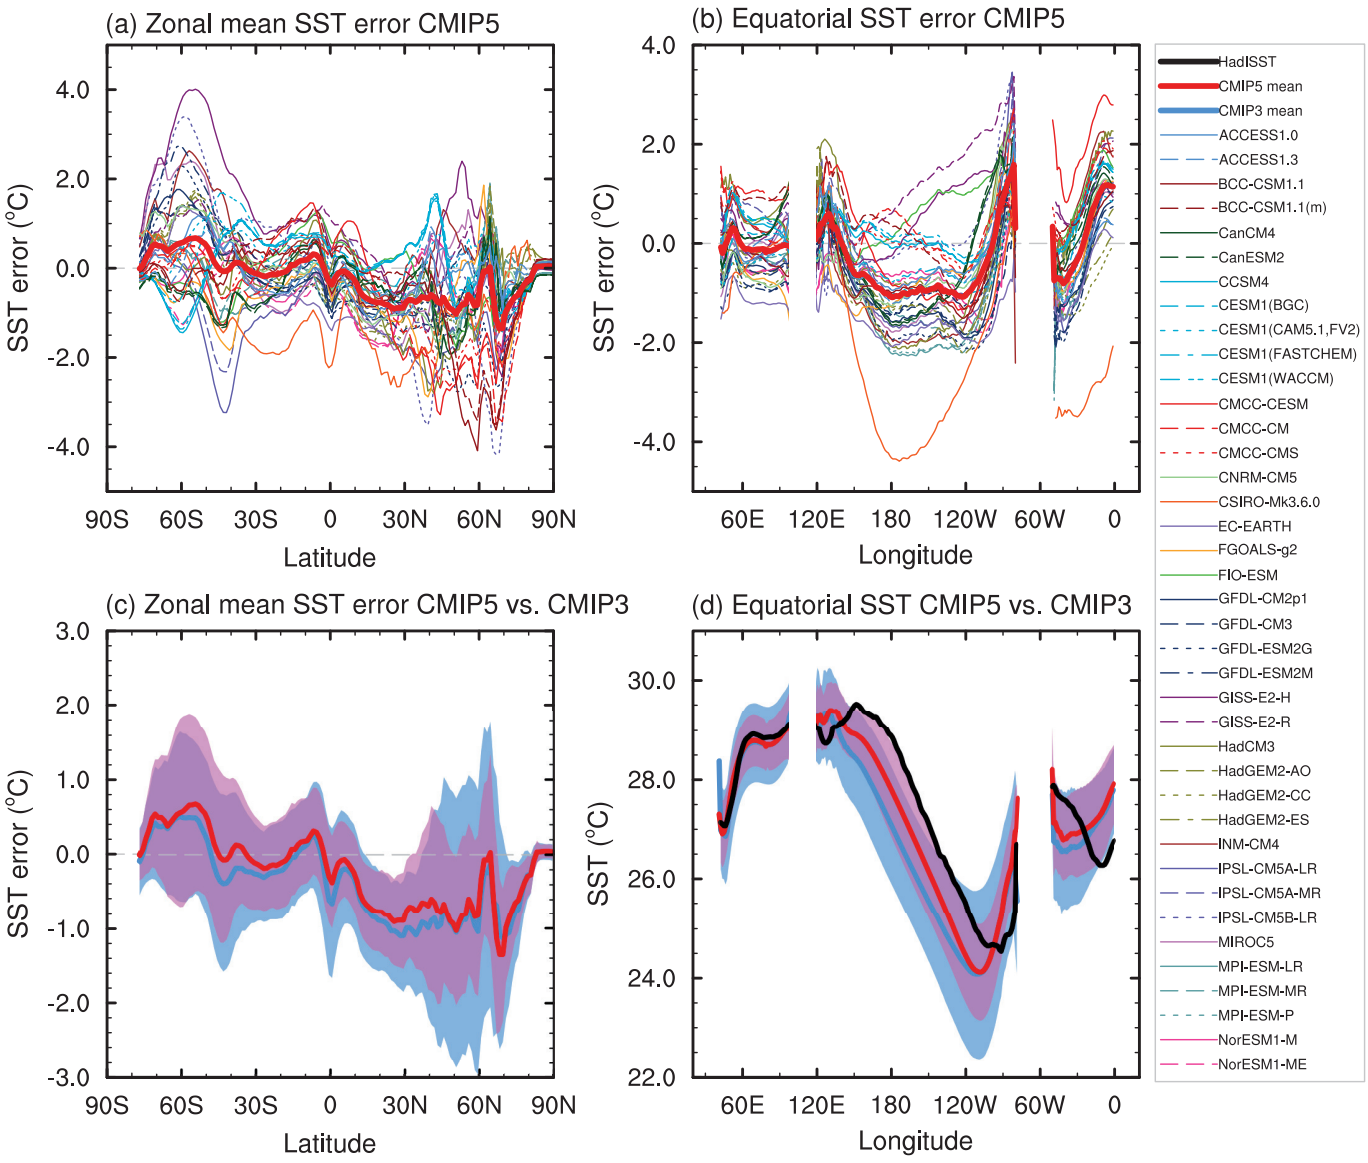

Figure 9.14 | (a) Zonally averaged sea surface temperature (SST) error in CMIP5 models. (b) Equatorial SST error in CMIP5 models. (c) Zonally averaged multi-model mean SST error for CMIP5 (red curve) and CMIP3 (blue curve), together with inter-model standard deviation (shading). (d) Equatorial multi-model mean SST in CMIP5 (red curve), CMIP3 (blue curve) together with inter-model standard deviation (shading) and observations (black). Model climatologies are derived from the 1979–1999 mean of the historical simulations. The Hadley Centre Sea Ice and Sea Surface Temperature (HadISST) (Rayner et al., 2003) observational climatology for 1979–1999 is used as reference for the error calculation (a), (b), and (c); and for observations in (d).

the Antarctic shelf, but it mixes with lighter water and is not exported as bottom water. Instead most models create deep water by open ocean deep convection, a process occurring rarely in reality (Heuzé et al., 2013) which leads to errors in deep water formation and properties in the Southern Ocean as shown in Figure 9.15.

Few studies have assessed the performance of models in simulating Mixed Layer Depth (MLD). In the North East Pacific region, Jang et al. (2011) found that the CMIP3 models exhibit the observed deep MLD in the Kuroshio Extension, though with a deep bias and only one large deep MLD region, rather than the observed two localized maxima. Other studies have noted MLD biases near sea ice edges (Capotondi et al., 2012).

9.4.2.2 Simulation of Sea Level and Ocean Heat Content

Steric and dynamic components of the mean dynamic topography (MDT) and sea surface height (SSH) patterns can be compared to observations (Maximenko et al., 2009). Pattern correlations between simulated and observed MDT are above 0.95 for all of the CMIP5 models (Figure 9.16), an improvement compared to CMIP3. MDT biases over tropical ocean regions are consistent with surface wind stress biases (Lee et al., 2013). Over the Antarctic Circumpolar Current, the parameterization of eddy-induced transports is essential for the models' density structure and thus MDT (Kuhlbrodt et al., 2012). High-resolution eddy resolving ocean models show improved SSH simulations over coarser resolution versions (McClean et al., 2006). Chapter 13 provides a more extensive

assessment of sea level changes in CMIP5 simulations, including comparisons with century-scale historical records.

Ocean heat content (OHC) depends only on ocean temperature, whereas absolute changes in sea level are also influenced by processes that are only now being incorporated into global models (e.g., mass loss from large ice sheets discussed in Section 9.1.3.2.7). However, global-scale changes in OHC are highly correlated with the thermosteric contribution to global SSH changes (Domingues et al., 2008). Approximately half of the historical CMIP3 simulations did not include the effects of volcanic eruptions, resulting in substantially greater than observed ocean heat uptake during the late 20th century (Gleckler et

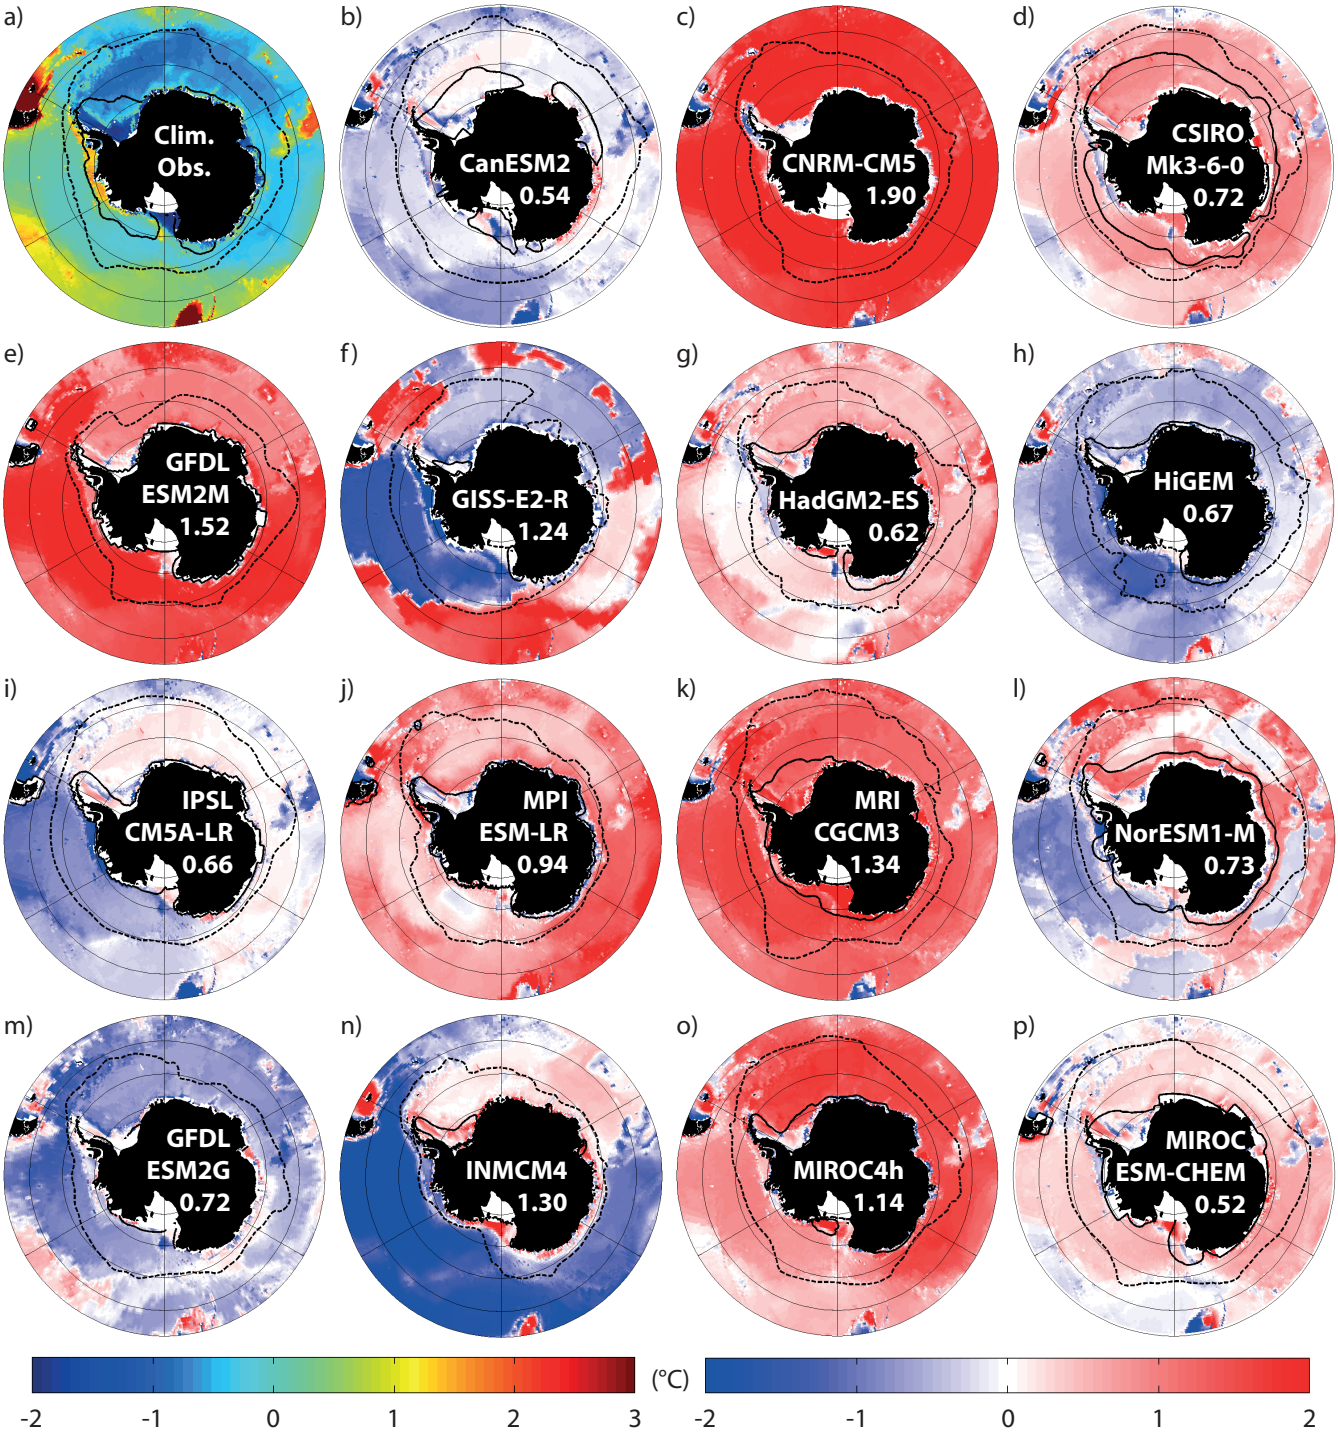

Figure 9.15 | Time-mean bottom potential temperature in the Southern Ocean, observed (a) and the differences between individual CMIP5 models and observations (b–p); left colour bar corresponds to the observations, right colour bar to the differences between model and observations (same unit). Thick dashed black line is the mean August sea ice extent (concentration >15%); thick continuous black line is the mean February sea ice extent (concentration >15%). Numbers indicate the area-weighted root-mean-square (RMS) error for all depths between the model and the climatology (unit °C); mean RMS error = 0.97 °C. (After Heuzé et al., 2013.)

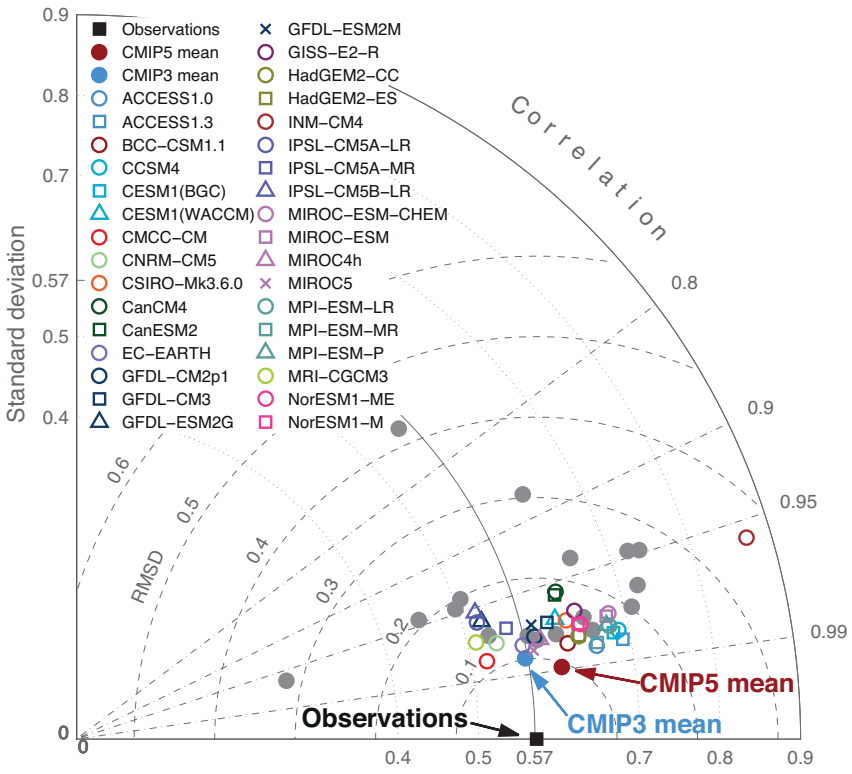

Figure 9.16 | Taylor diagram for the dynamic sea surface height climatology (1987–2000). The radial coordinate shows the standard deviation of the spatial pattern, normalized by the observed standard deviation. The azimuthal variable shows the correlation of the modelled spatial pattern with the observed spatial pattern. The root-mean square error with bias removed is indicated by the dashed grey circles about the observational point. Analysis is for the global ocean, 50°S to 50°N. The reference data set is Archiving, Validation and Interpretation of Satellite Oceanographic data (AVISO), a merged satellite product (Ducet et al., 2000), which is described in Chapter 3. One realization per model is shown for each CMIP5 and CMIP3 model result. Grey filled circles are for individual CMIP3 models; other symbols as in legend.

al., 2006; Domingues et al., 2008). Figure 9.17 shows observed and simulated global 0 to 700 m and total OHC changes during the overlap period of the observational record and the CMIP5 historical experiment (1961–2005). Three upper-ocean observational estimates, assessed in Chapter 3, are also shown to indicate observational uncertainty. The CMIP5 multi-model mean falls within the range of observations for most of the period, and the intermodel spread is reduced relative to CMIP3 (Gleckler et al., 2006; Domingues et al., 2008). This may result from most CMIP5 models including volcanic forcings. When the deep ocean is included, the CMIP5 multi-model mean also agrees well with the observations, although the deeper ocean estimates are much more uncertain (Chapter 3). There is *high confidence* that many CMIP5 models reproduce the observed increase in ocean heat content since 1960.

EMIC results for changes in total OHC are also compared with observations in Figure 9.17. (Note: results in this figure are based on Eby et al. (2013) who show OHC changes for 0 to 2000 m, whereas here the time-integrated net heat flux into the ocean surface is shown to compare with CMIP5 results (Figure 9.17b)). There is a tendency for the EMICs to overestimate total OHC changes and this could alter the temperature related feedbacks on the oceanic carbon cycle, and affect the long-term millennium projections in Chapter 12. However, it should be noted that high OHC changes can compensate for biases in climate sensitivity or RF so as to reproduce surface temperature changes over the 20th century. This will result in biased thermosteric sea level rise for millennial projections. Calibrated EMICs (Meinshausen et al., 2009; Sokolov et al., 2010) would remove such biases.

In idealized CMIP5 experiments (CO_2 increasing 1% yr^{-1}), the heat uptake efficiency of the CMIP5 models varies by a factor of two, explaining about 50% of the model spread (Kuhlbrodt and Gregory, 2012). Despite observational uncertainties, this recent work also provides *limited evidence* that in the upper 2000 m, most CMIP5 models are less stratified (in the global mean) than is observed, which suggests that these models transport heat downwards more efficiently than the real ocean. These results are consistent with earlier studies (Forest et al., 2006, 2008; Boe et al., 2009a; Sokolov et al., 2010) that conclude the CMIP3 models may overestimate oceanic mixing efficiency and therefore underestimate the Transient Climate Response (TCR) and its impact on future surface warming. However, Kuhlbrodt and Gregory (2012) also find that this apparent bias explains very little of the model spread in TCR. Although some progress has been made in understanding mixing deficiencies in ocean models (Griffies and Greatbatch, 2012; Ilicak et al., 2012), this remains a key challenge in improving the representation of physical processes that impact the evolution of ocean heat content and thermal expansion.

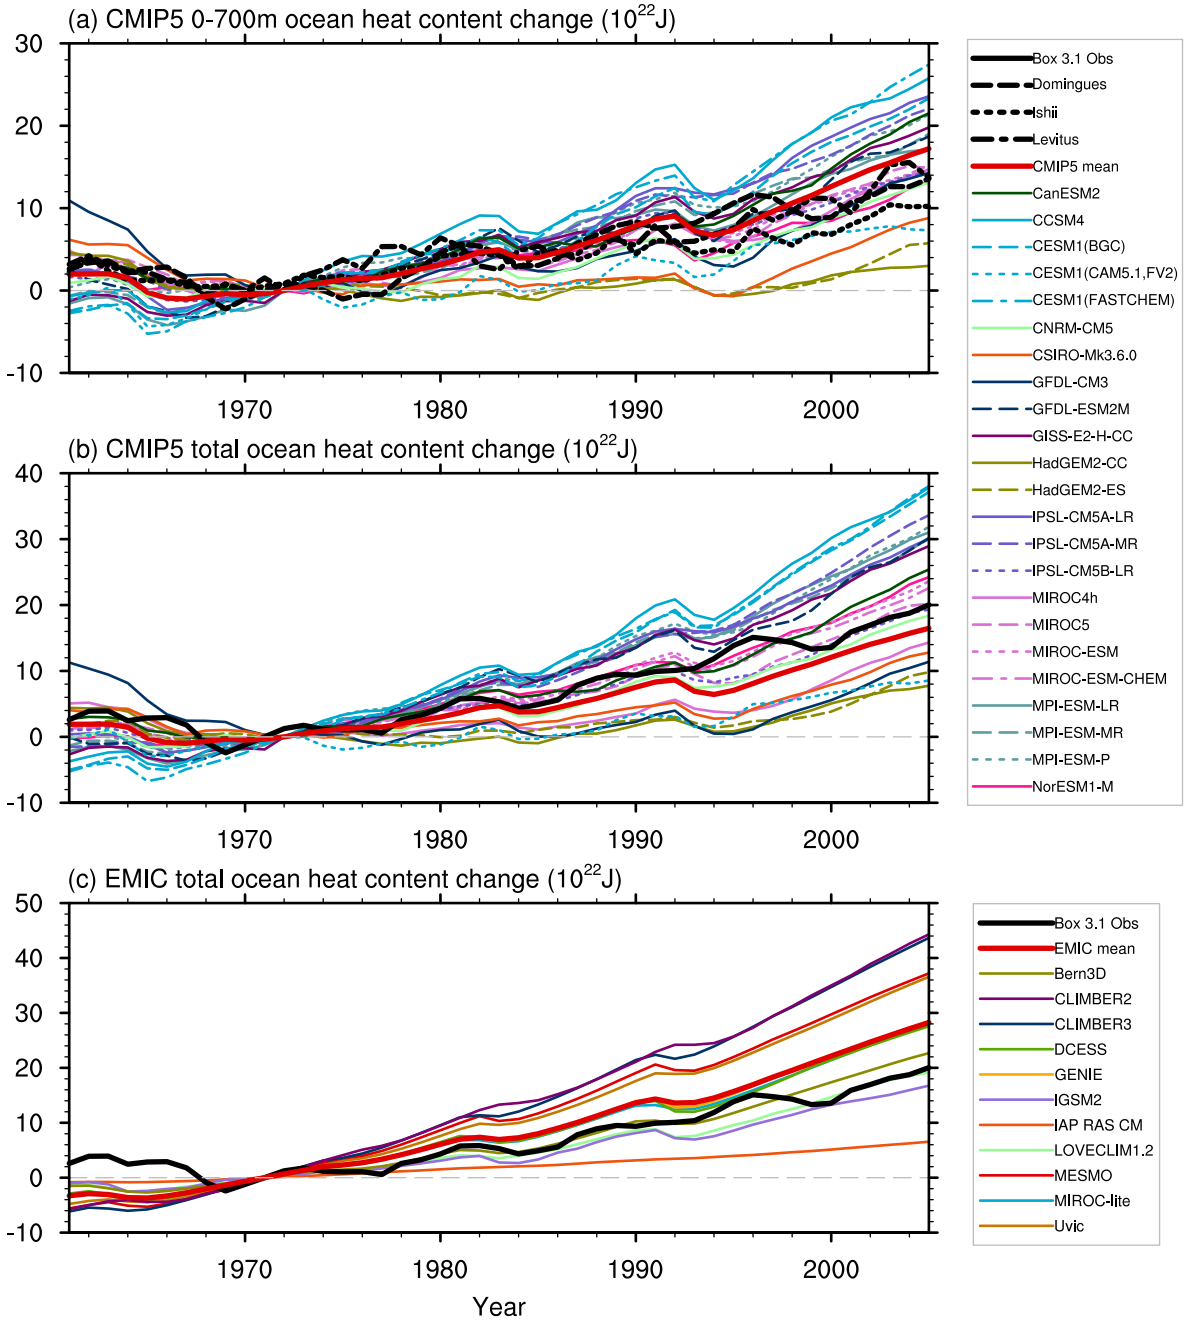

Figure 9.17 | Time series of simulated and observed global ocean heat content anomalies (with respect to 1971). CMIP5 historical simulations and observations for both the upper 700 meters of the ocean (a) as well as for the total ocean heat content (b). Total ocean heat content results are also shown for EMICs and observations (c). EMIC estimates are based on time-integrated surface heat flux into the ocean. The 0 to 700 m and total heat content observational estimates (thick lines) are respectively described in Figure 3.2 and Box 3.1, Figure 1. Simulation drift has been removed from all CMIP5 runs with a contemporaneous portion of a quadratic fit to each corresponding pre-industrial control run (Gleckler et al., 2012). Units are 10^{22} Joules.

9.4.2.3 Simulation of Circulation Features Important for Climate Response

9.4.2.3.1 Simulation of recent ocean circulation

Atlantic Meridional Overturning Circulation

The Atlantic Meridional Overturning Circulation (AMOC) consists of northward transport of shallow warm water overlying a southward transport of deep cold water and is responsible for a considerable part of the northward oceanic heat transport. Long-term AMOC estimates have had to be inferred from hydrographic measurements sporadically available over the last decades (e.g., Bryden et al., 2005; Lumpkin et al., 2008, Chapter 3.6.3). Continuous AMOC monitoring at 26.5°N was started in 2004 (Cunningham et al., 2007) and now provides a 5-year mean value of 18.5 Sv with annual means having a standard deviation of 1 Sv (McCarthy et al., 2012). The ability of models to simulate this important circulation feature is tied to the credibility of simulated AMOC weakening during the 21st century because the magnitude of

the weakening is correlated with the initial AMOC strength (Gregory et al., 2005). The mean AMOC strength in CMIP5 models ranges from 15 to 30 Sv for the historical period which is comparable to the CMIP3 models (Weaver et al., 2012; see Figure 12.35). The variability of the AMOC is assessed in Section 9.5.3.3.1.

Southern Ocean circulation

The Southern Ocean is an important driver for the meridional overturning circulation and is closely linked to the zonally continuous Antarctic Circumpolar Current (ACC). Gupta et al. (2009) noted that relatively small deficiencies in the position of the ACC lead to more obvious biases in the SST in the models. The ability of CMIP3 models to adequately represent Southern Ocean circulation and water masses seems to be affected by several factors (Russell et al., 2006). The most important are the strength of the westerlies at the latitude of the Drake Passage, the heat flux gradient over this region, and the change in salinity with depth across the ACC. Kuhlbrodt et al. (2012) found that the strongest influence on ACC transport in the CMIP3 models was the Gent-McWilliams thickness diffusivity. The ACC has a typical transport through the Drake Passage of about 135 Sv (e.g., Cunningham et al., 2003). A comparison of CMIP5 models (Meijers et al., 2012) shows that, firstly, the ACC transport through Drake Passage is improved as compared to the CMIP3 models, and secondly, that the inter-model range in the zonal mean ACC position is smaller than in the CMIP3 ensemble (in CMIP5, the mean transport is 148 Sv and the standard deviation is 50 Sv across an ensemble of 21 models).

Simulation of glacial ocean conditions

Reconstructions of the last glacial maximum from sediment cores discussed in Chapter 5 indicate that the regions of deep water formation in the North Atlantic were shifted southward, that the boundary between North Atlantic Deep Water (NADW) and Antarctic Bottom Water (AABW) was substantially shallower than today, and that NADW formation was less intense (Duplessy et al., 1988; Dokken and Jansen, 1999; McManus et al., 2004; Curry and Oppo, 2005). This signal, although estimated from a limited number of sites, is robust (see Chapter 5). The AR4 reported that model simulations showed a wide range of AMOC response to LGM forcing (Weber et al., 2007), with some models exhibiting reduced strength of the AMOC and its extension at depth and other showing no change or an increase. Figure 9.18 provides an update of the diagnosis proposed by Otto-Bliesner et al. (2007) to compare model results with the deep ocean data from Adkins et al. (2002) using PMIP2 and CMIP5/PMIP3 pre-industrial and LGM simulations (Braconnot et al., 2012). These models reproduce the modern deep ocean temperature–salinity (T–S) structure in the Atlantic basin, but most of them do not capture the cold and salty bottom

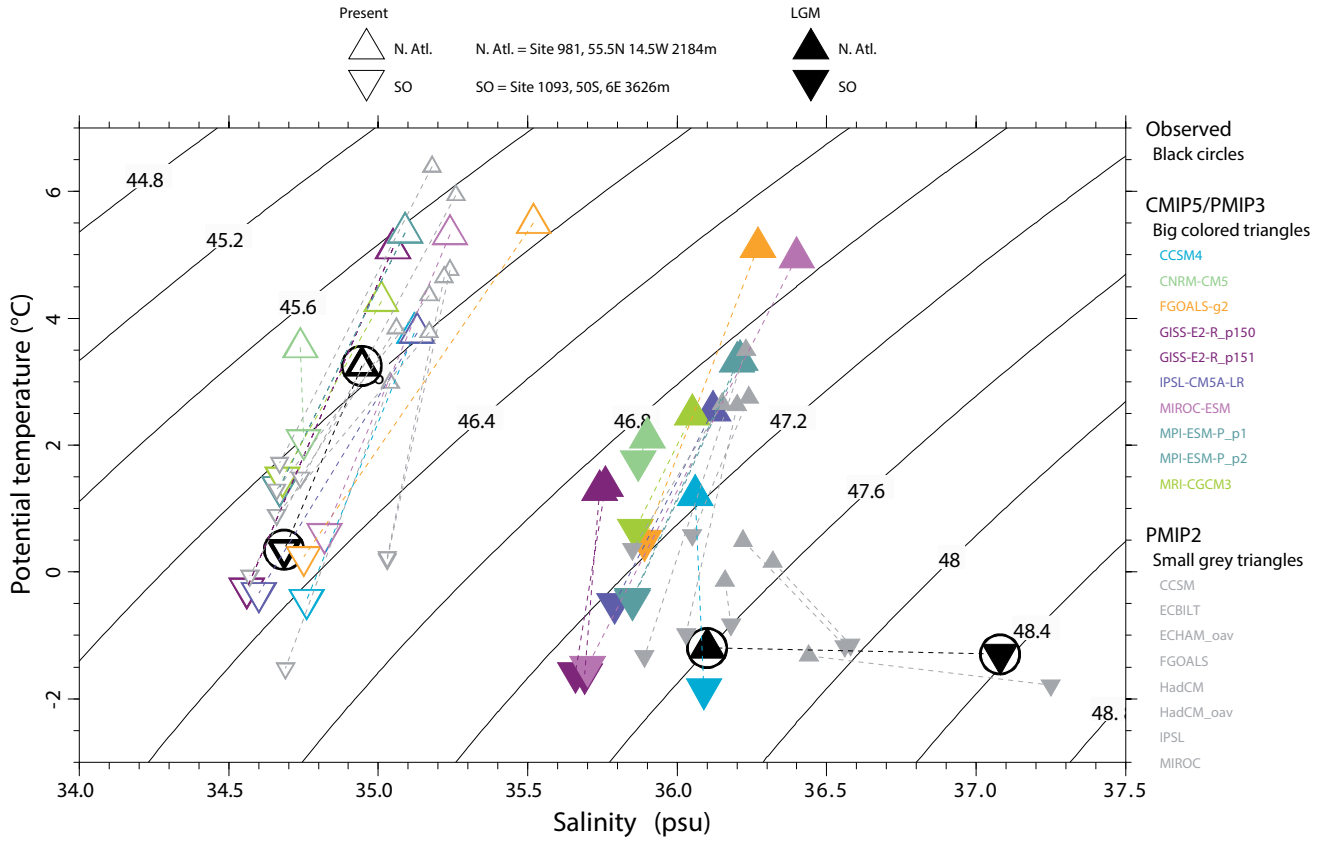

Figure 9.18 | Temperature and salinity for the modern period (open symbols) and the Last Glacial Maximum (LGM, filled symbols) as estimated from proxy data at Ocean Drilling Program (ODP) sites (black symbols, from Adkins et al., 2002) and simulated by the Paleoclimate Modelling Intercomparison Project version 2 (PMIP2, small triangles) and PMIP3/CMIP5 (big triangles) models. The isolines represent lines of equal density. Site 981 (triangles) is located in the North Atlantic (Feni Drift, 55°N, 15°W, 2184 m). Site 1093 (upside-down triangles) is located in the South Atlantic (Shona Rise, 50°S, 6°E, 3626 m). In PMIP2, only Community Climate System Model (CCSM) included a 1 psu adjustment of ocean salinity at initialization to account for freshwater frozen into LGM ice sheets; the other PMIP2 model-simulated salinities have been adjusted to allow a comparison. In PMIP3, all simulations include the 1 psu adjustment as required in the PMIP2/CMIP5 protocol (Braconnot et al., 2012). The dotted lines allow a comparison of the values at the NH and SH sites for a same model. This figure is adapted from Otto-Bliesner et al. (2007).

water suggested by the LGM reconstructions, providing evidence that processes responsible for such palaeoclimate changes may not be well reproduced in contemporary climate models. This is expected to also affect projected changes in deep ocean properties.

9.4.2.4 Simulation of Surface Fluxes and Meridional Transports

Surface fluxes play a large part in determining the fidelity of ocean simulations. As noted in the AR4, large uncertainties in surface heat and fresh water flux observations (usually obtained indirectly) do not allow useful evaluation of models. This is still the case and so the focus here is on an integrated quantity, meridional heat transport, which is less prone to errors. Surface wind stress is better observed and models are evaluated against observed products below.

The zonal component of wind stress is particularly important in driving ocean surface currents; modelled and observed values are shown in Figure 9.19. At middle to high latitudes, the model-simulated wind stress maximum lies 5 to 10 degree equatorward of that in the observationally based estimates, and so mid-latitude westerly winds are

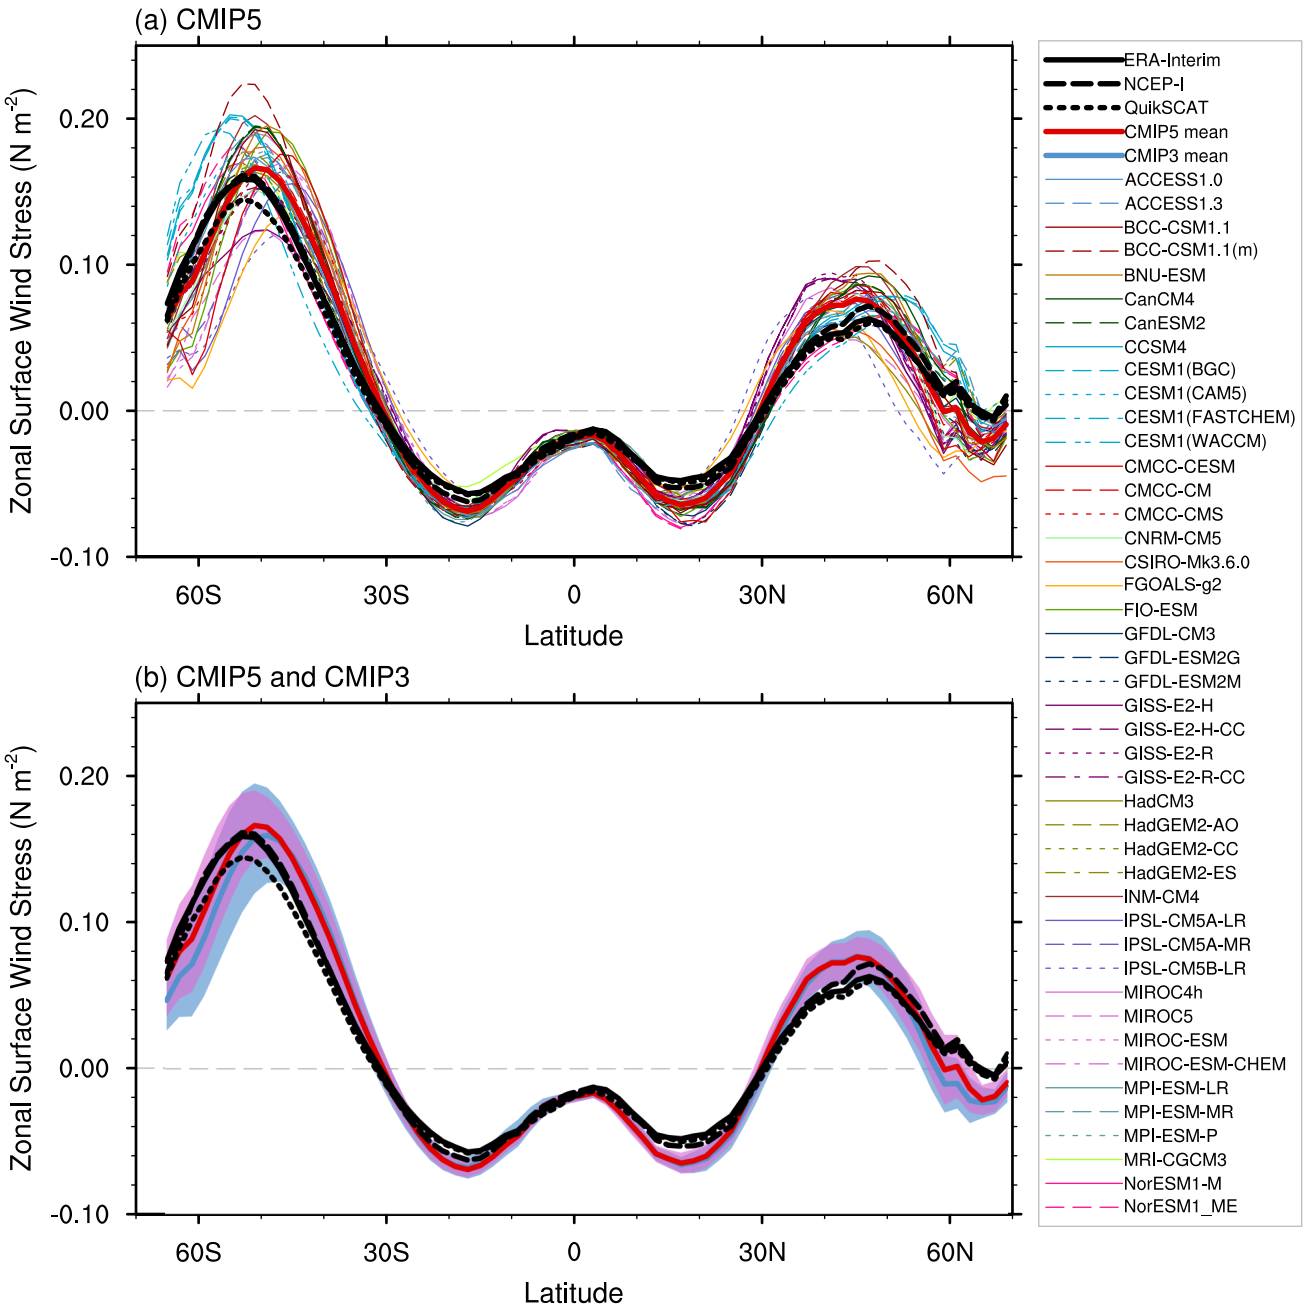

Figure 9.19 | Zonal-mean zonal wind stress over the oceans in (a) CMIP5 models and (b) multi-model mean comparison with CMIP3. Shown is the time-mean of the period 1970–1999 from the historical simulations. The black solid, dashed, and dotted curves represent ECMWF reanalysis of the global atmosphere and surface conditions (ERA)-Interim (Dee et al., 2011), National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR) reanalysis I (Kalnay et al., 1996), and QuikSCAT satellite measurements (Risien and Chelton, 2008), respectively. In (b) the shading indicates the inter-model standard deviation.

too strong in models. This equatorward shift in the southern ocean is slightly reduced in CMIP5 relative to CMIP3. At these latitudes, the largest near surface wind speed biases in CMIP5 are located over the Pacific sector and the smallest are in the Atlantic sector (Bracegirdle et al., 2013). Such wind stress errors may adversely affect oceanic heat and carbon uptake (Swart and Fyfe, 2012a). At middle to low latitudes, the CMIP3 and CMIP5 model spreads are smaller than at high latitudes, although near the equator this can occur through compensating errors (Figure 9.20). The simulated multi-model mean equatorial zonal wind stress is too weak in the Atlantic and Indian Oceans and too strong in the western Pacific, with no major improvement from CMIP3 to CMIP5.

The CMIP5 model simulations qualitatively agree with the various observational estimates on the most important features of ocean heat transport (Figure 9.21) and, in a multi-model sense, no major change from CMIP3 can be seen. All CMIP5 models are able to the represent the strong north-south asymmetry, with the largest values in the NH, consistent with the observational estimates. At most latitudes the majority of CMIP5 model results fall within the range of observational estimates,

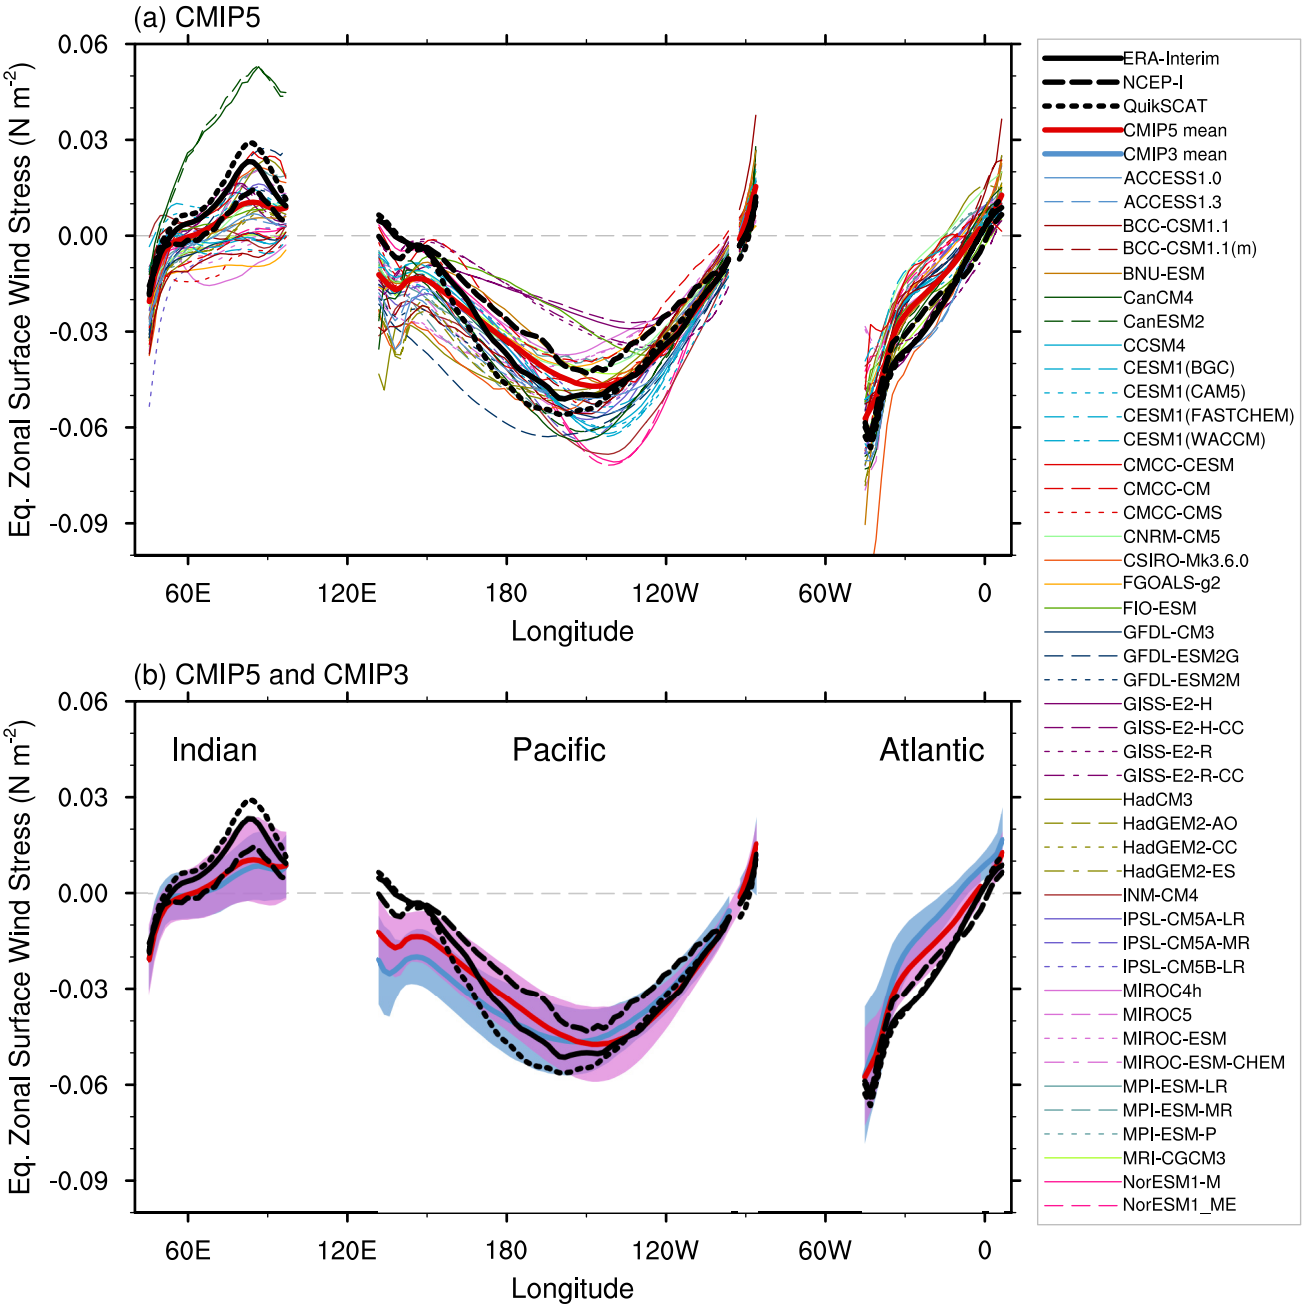

Figure 9.20 | Equatorial (2°S to 2°N averaged) zonal wind stress for the Indian, Pacific, and Atlantic oceans in (a) CMIP5 models and (b) multi-model mean comparison with CMIP3. Shown is the time-mean of the period 1970–1999 from the historical simulations. The black solid, dashed, and dotted curves represent ERA-Interim (Dee et al., 2011), National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR) reanalysis I (Kalnay et al., 1996) and QuikSCAT satellite measurements (Risien and Chelton, 2008), respectively. In (b) the shading indicates the inter-model standard deviation.

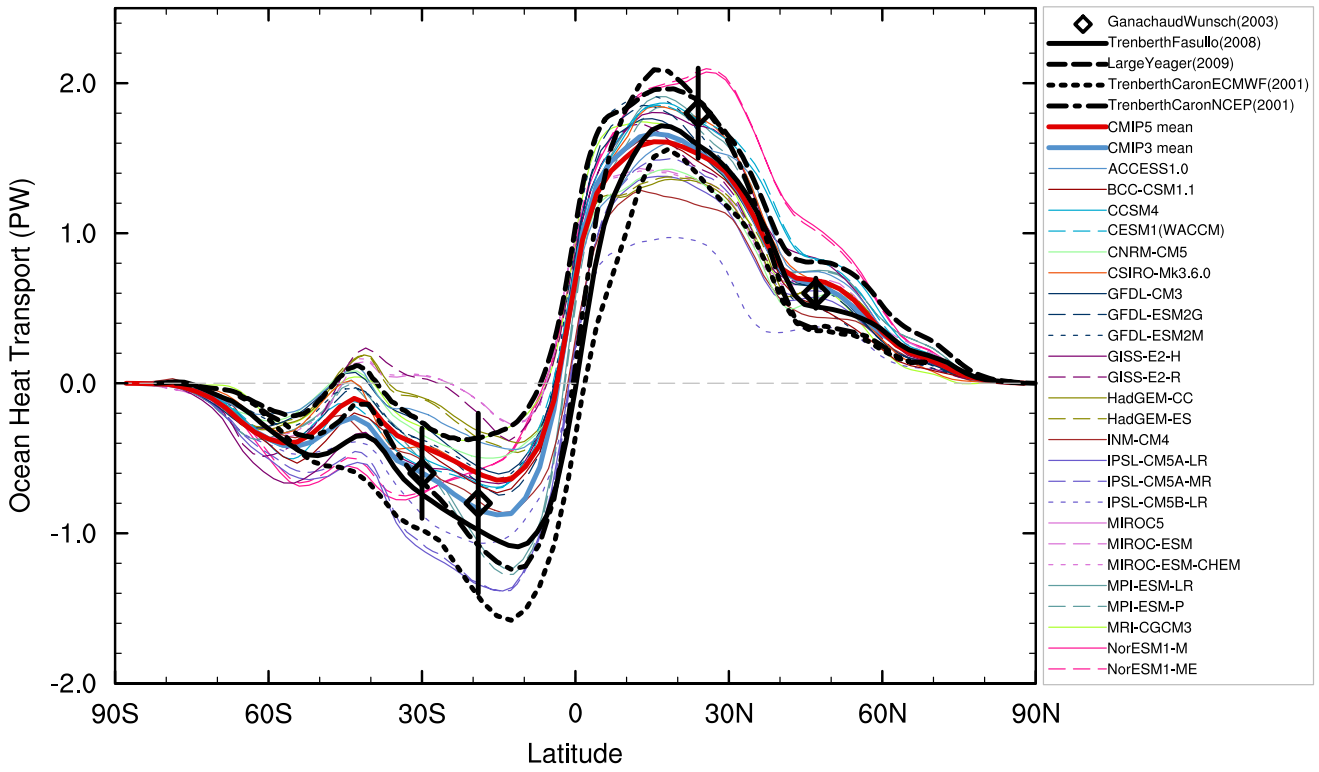

Figure 9.21 | Annual- and zonal-mean oceanic heat transport implied by net heat flux imbalances at the sea surface for CMIP5 simulations, under an assumption of negligible changes in oceanic heat content. Observational estimates include: the data set from Trenberth and Caron (2001) for the period February 1985 to April 1989, derived from reanalysis products from the National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR; Kalnay et al., 1996; dash-dotted black) and European Centre for Medium Range Weather Forecasts 40-year reanalysis (ERA40; Uppala et al., 2005; short-dashed black), an updated version by Trenberth and Fasullo (2008) with improved top of the atmosphere (TOA) radiation data from the Clouds and Earth's Radiant Energy System (CERES) for March 2000 to May 2004, and updated NCEP reanalysis (Kistler et al., 2001) up to 2006 (solid black), the Large and Yeager (2009) analysis based on the range of annual mean transport estimated over the years 1984–2006, computed from air–sea surface fluxes adjusted to agree in the mean with a variety of satellite and *in situ* measurements (long-dashed black), and direct estimates by Ganachaud and Wunsch (2003) obtained from hydrographic sections during the World Ocean Circulation Experiment combined with inverse models (black diamonds). The model climatologies are derived from the years 1986 to 2005 in the historical simulations in CMIP5. The multi-model mean is shown as a thick red line. The CMIP3 multi-model mean is added as a thick blue line.

although there is some suggestion of modest underestimate between 15°N and 25°N and south of about 60°S. Some models show an equatorward transport at Southern-Hemisphere mid-latitudes that is also featured in the observation estimate of Large and Yeager (2009). This highlights the difficulties in representing large-scale energy processes in the Southern ocean as discussed by Trenberth and Fasullo (2010b). Note that climate models should exhibit a vanishing net energy balance when long time averages are considered but unphysical sources and sinks lead to energy biases (Trenberth and Fasullo, 2009, 2010a; Lucarini and Ragone, 2011) that are also found in reanalysis constrained by observations (Trenberth et al., 2009). When correcting for the imperfect closure of the energy cycle, as done here, comparison between models and observational estimates become possible.

9.4.2.5 Simulation of Tropical Mean State

9.4.2.5.1 Tropical Pacific Ocean

Although the basic east–west structure of the tropical Pacific is well captured, models have shown persistent biases in important properties of the mean state (AchutaRao and Sperber, 2002; Randall et al., 2007; Guilyardi et al., 2009b) with severe local impacts (Brown et al., 2012). Among these biases are the mean thermocline depth and slope along the equator, the structure of the equatorial current system, and the excessive equatorial cold tongue (Reichler and Kim, 2008; Brown et al., 2010a; Zheng et al., 2012). Many reasons for these biases have been proposed, such as: too strong trade winds; a too diffusive thermocline; deficient horizontally isotropic mixing coefficients; insufficient penetration of solar radiation; and too weak tropical instability waves (Meehl et al., 2001; Wittenberg et al., 2006; Lin, 2007). It is noteworthy that CMIP5 models exhibit some improvements in the western equatorial Pacific when compared to CMIP3, with reduced SST and trade wind errors (Figures 9.14 and 9.20). Because of strong interactions between the processes involved, it is difficult to identify the ultimate source of these errors, although new approaches using the rapid adjustment of initialized simulations hold promise (Vannière et al., 2011).

A particular problem in simulating the seasonal cycle in the tropical Pacific arises from the 'double ITCZ', defined as the appearance of a spurious ITCZ in the SH associated with excessive tropical precipitation. Further problems are too strong a seasonal cycle in simulated SST and winds in the eastern Pacific and the appearance of a spurious semi-annual cycle. The latter has been attributed to meridional asymmetry in the background state that is too weak, possibly in conjunction with incorrect regional water vapour feedbacks (Li and Philander, 1996; Guilyardi, 2006; Timmermann et al., 2007; De Szoeke and Xie, 2008; Wu et al., 2008a; Hirota et al., 2011).

A further persistent problem is insufficient marine stratocumulus cloud in the eastern tropical Pacific, caused presumably by weak coastal upwelling off South America leading to a warm SST bias (Lin, 2007). Although the problem persists, improvements are being made (Achuta-Rao and Sperber, 2006).

9.4.2.5.2 Tropical Atlantic Ocean

CMIP3 and CMIP5 models exhibit severe biases in the tropical Atlantic Ocean, so severe that some of the most fundamental features—the east–west SST gradient and the eastward shoaling thermocline along the equator—cannot be reproduced (Figure 9.14; (Chang et al., 2007; Chang et al., 2008; Richter and Xie, 2008; Richter et al., 2013). In many models, the warm SST bias along the Benguela coast is in excess of 5°C and the Atlantic warm pool in the western basin is grossly underestimated (Liu et al., 2013a). As in the Pacific, CMIP3 models suffer the double ITCZ error in the Atlantic. Hypotheses for the complex Atlantic bias problem tend to draw on the fact that the Atlantic Ocean has a far smaller basin, and thus encourages a tighter and more complex land–atmosphere–ocean interaction. A recent study using a high-resolution coupled model suggests that the warm eastern equatorial Atlantic SST bias is more sensitive to the local rather than basin-wide trade wind bias and to a wet Congo basin instead of a dry Amazon—a finding that differs from previous studies (Patricola et al., 2012). Recent ocean model studies show that a warm subsurface temperature bias in the eastern equatorial Atlantic is common to virtually all ocean models forced with 'best estimated' surface momentum and heat fluxes, owing to problems in parameterization of vertical mixing (Hazeleger and Haarsma, 2005). Toniazzo and Woolnough (2013) show that among a variety of causes for the initial bias development, ocean–atmosphere coupling is key for their maintenance.

9.4.2.5.3 Tropical Indian Ocean

CMIP3 and CMIP5 models simulate equatorial Indian Ocean climate reasonably well (e.g., Figure 9.14), though most models produce weak westerly winds and a flat thermocline on the equator. The models show a large spread in the modelled depth of the 20°C isotherm in the eastern equatorial Indian Ocean (Saji et al., 2006). The reasons are unclear but may be related to differences in the various parameterizations of vertical mixing as well as the wind structure (Schott et al., 2009).

CMIP3 models generally simulate the Seychelles Chagos thermocline ridge in the Southwest Indian Ocean, a feature important for the Indian monsoon and tropical cyclone activity in this basin (Xie et al., 2002). The models, however, have significant problems in accurately representing its seasonal cycle because of the difficulty in capturing the asymmetric nature of the monsoonal winds over the basin, resulting in too weak a semi-annual harmonic in the local Ekman pumping over the ridge region compared to observations (Yokoi et al., 2009b). In about half of the models, the thermocline ridge is displaced eastward associated with the easterly wind biases on the equator (Nagura et al., 2013).

9.4.2.6 Summary

There is *high confidence* that the CMIP3 and CMIP5 models simulate the main physical and dynamical processes at play during transient ocean heat uptake, sea level rise, and coupled modes of variability. There is little evidence that CMIP5 models differ significantly from CMIP3, although there is some evidence of modest improvement. Many improvements are seen in individual CMIP5 ocean components (some now including interactive ocean biogeochemistry) and the number of relatively poor-performing models has been reduced (thereby reducing inter-model spread). New since the AR4, process-based model evaluation is now helping identify the cause of some specific biases, helping to overcome the limits set by the short observational records available.

9.4.3 Sea Ice

Evaluation of sea ice performance requires accurate information on ice concentration, thickness, velocity, salinity, snow cover and other factors. The most reliably measured characteristic of sea ice remains sea ice extent (usually understood as the area covered by ice with a concentration above 15%). Caveats, however, exist related to the uneven reliability of different sources of sea ice extent estimates (e.g., satellite vs. pre-satellite observations; see Chapter 4), as well as to limitations of this characteristic as a metric of model performance (Notz et al., 2013).

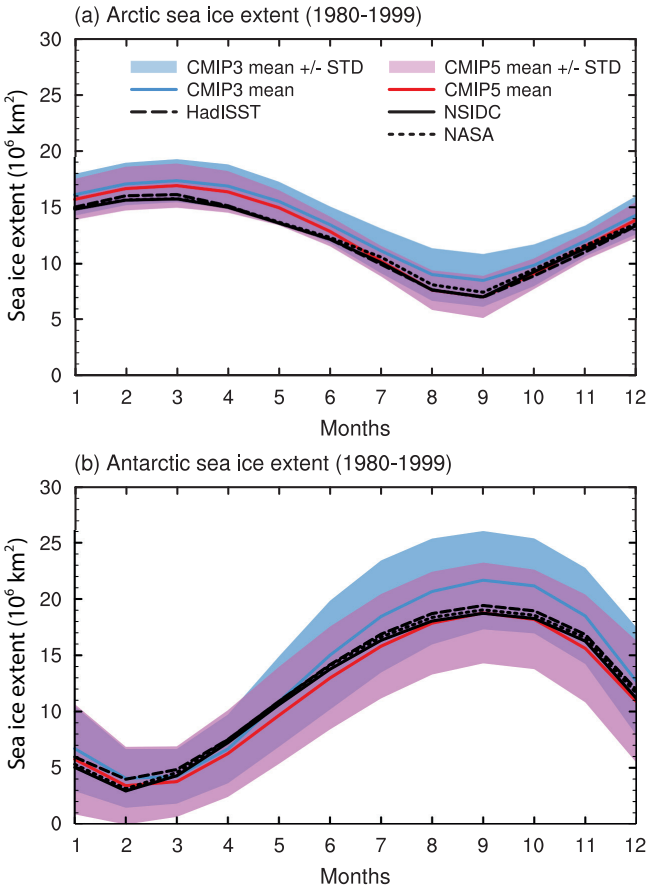

Figure 9.22 | Mean (1980–1999) seasonal cycle of sea ice extent (the ocean area with a sea ice concentration of at least 15%) in the Northern Hemisphere (upper) and the Southern Hemisphere (lower) as simulated by 42 CMIP5 and 17 CMIP3 models. Each model is represented with a single simulation. The observed seasonal cycles (1980–1999) are based on the Hadley Centre Sea Ice and Sea Surface Temperature (HadISST; Rayner et al., 2003), National Aeronautics and Space Administration (NASA; Comiso and Nishio, 2008) and the National Snow and Ice Data Center (NSIDC; Fetterer et al., 2002) data sets. The shaded areas show the inter-model standard deviation for each ensemble. (Adapted from Pavlova et al., 2011.)

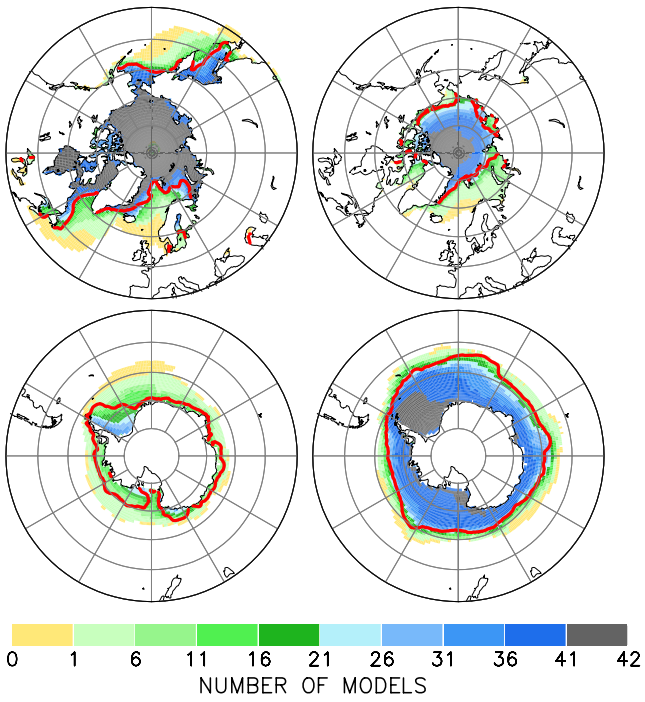

Figure 9.23 | Sea ice distribution (1986–2005) in the Northern Hemisphere (upper panels) and the Southern Hemisphere (lower panels) for February (left) and September (right). AR5 baseline climate (1986–2005) simulated by 42 CMIP5 AOGCMs. Each model is represented with a single simulation. For each 1° × 1° longitude-latitude grid cell, the figure indicates the number of models that simulate at least 15% of the area covered by sea ice. The observed 15% concentration boundaries (red line) are based on the Hadley Centre Sea Ice and Sea Surface Temperature (HadISST) data set (Rayner et al., 2003). (Adapted from Pavlova et al., 2011.)

The CMIP5 multi-model ensemble exhibits improvements over CMIP3 in simulation of sea ice extent in the both hemispheres (Figure 9.22). In the Arctic, the multi-model mean error do not exceed 10% of the observationally based estimates for any given month. In the Antarctic, the corresponding multi-model mean error exceeds 10% (but is less than 20%) near the annual minimum of sea ice extent; around the annual maximum, the CMIP5 multi-model mean shows a clear improvement over CMIP3.

In many models the regional distribution of sea ice concentration is poorly simulated, even if the hemispheric extent is approximately correct. In Figure 9.23, however, one can see that the median ice edge position (indicated by the colour at which half of the models have ice of 15% concentration) agrees reasonably well with observations in both hemispheres (except austral summer in Antarctica), as was the case for the CMIP3 models.

A widely discussed feature of the CMIP3 models as a group is a pronounced underestimation of the trend in the September (annual minimum) sea ice extent in the Arctic over the past several decades (e.g., Stroeve et al., 2007; Zhang, 2010; Rampal et al., 2011; Winton, 2011). Possible reasons for the discrepancy include variability inherent to high latitudes, model shortcomings, and observational uncertainties (e.g., Kattsov et al., 2010; Kay et al., 2011; Day et al., 2012). Compared to CMIP3, the CMIP5 models better simulate the observed trend of September Arctic ice extent (Figure 9.24). It has been suggested (Stroeve et al., 2012) that in some cases model improvements, such as new sea ice albedo parameterization schemes (e.g., Pedersen et al., 2009; Holland et al., 2012), have been responsible. (Holland et al., 2010) show that models with initially thicker ice generally retain more extensive ice throughout the 21st century, and indeed several of the CMIP5 models start the 20th century with rather thin winter ice cover promoting more rapid melt (Stroeve et al., 2012). Notz et al. (2013) caution, however, against direct comparison of modelled trends with observations unless the models' internal variability is carefully taken into account. Their analysis of the MPI-ESM ensemble shows that internal variability in the Arctic can result in individual model realizations exhibiting a range of trends (negative, or even positive) for the 29-year-long period starting in 1979, even if the background climate is warming. According to the distribution of sea ice extent trends over the period 1979–2010 obtained in an ensemble of simulations with individual CMIP5 models (Figure 9.24) about one quarter of the simulations shows a September trend in the Arctic as strong as, or stronger, than in observations.

The majority of CMIP5 (and CMIP3) models exhibit a decreasing trend in SH austral summer sea ice extent over the satellite era, in contrast to the observed weak but significant increase (see Chapter 4). A large spread in the modelled trends is present, and a comparison of multiple ensemble members from the same model suggests large internal variability during the late 20th century and the first decade of the 21st century (e.g., Landrum et al., 2012; Zunz et al., 2013). Compared to observations, CMIP5 models strongly overestimate the variability of sea ice extent, at least in austral winter (Zunz et al., 2013).Therefore, using the models to assess the potential role of the internal variability in the trend of sea ice extent in the Southern Ocean over the last three decades presents a significant challenge.

Sea ice is a product of atmosphere–ocean interaction. There are a number of ways in which sea ice is influenced by and interacts with the atmosphere and ocean, and some of these feedbacks are still poorly quantified. As noted in the AR4, among the primary causes of biases in simulated sea ice extent, especially its geographical distribution, are problems with simulating high-latitude winds, ocean heat advection and mixing. For example, Koldunov et al. (2010) have shown, for a particular CMIP3 model, that significant ice thickness errors originate from biases in the atmospheric component. Similarly, Melsom et al. (2009) note sea ice improvements associated with improved description of heat transport by ocean currents. Biases imparted on modelled sea ice, common to many models, may also be related to representation of high-latitude processes (e.g., polar clouds) or processes not yet commonly included in models (e.g., deposition of carbonaceous aerosols on snow and ice). Some CMIP5 models show improvements in simulation of sea ice that are connected to improvements in simulation of the atmosphere (e.g., Notz et al., 2013).

9.4.3.1 Summary

CMIP5 models reproduce the seasonal cycle of sea ice extent in both hemispheres. There is *robust evidence* that the downward trend in Arctic summer sea ice extent is better simulated than at the time of the AR4, with about one quarter of the simulations showing a trend as strong as, or stronger than, that observed over the satellite era. The performance improvements are not only a result of improvements in

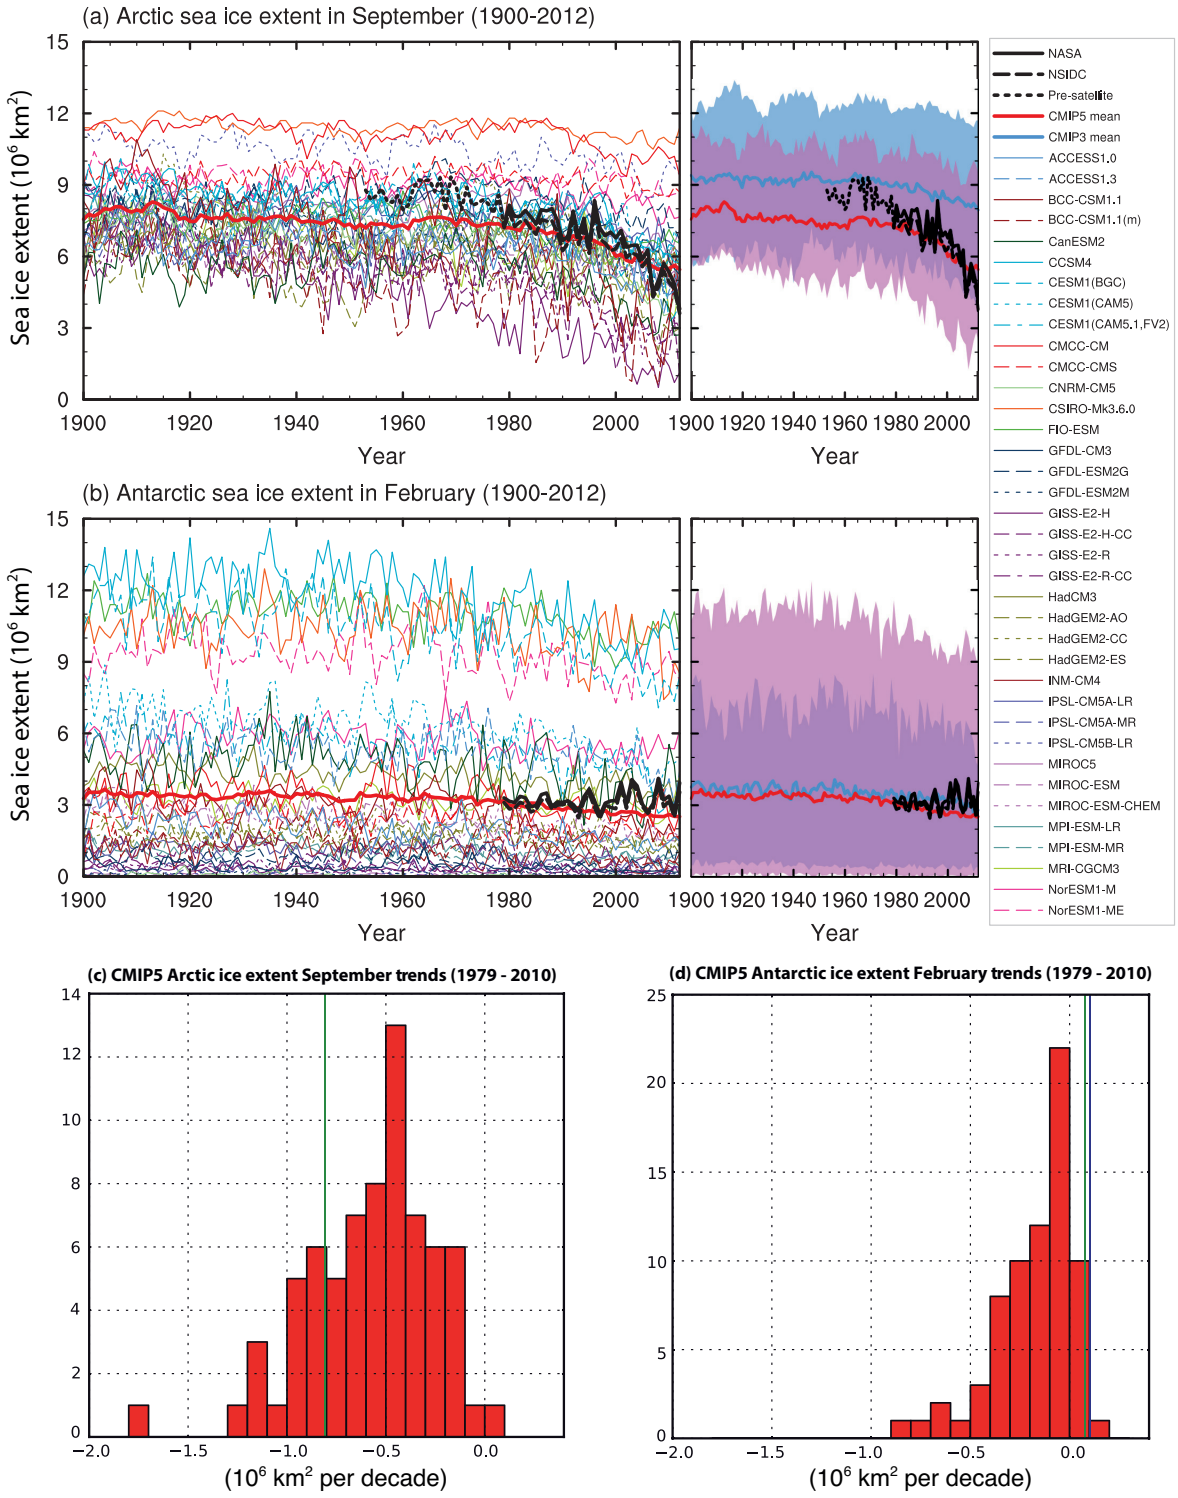

Figure 9.24 | (Top and middle rows) Time series of sea ice extent from 1900 to 2012 for (a) the Arctic in September and (b) the Antarctic in February, as modelled in CMIP5 (coloured lines) and observations-based (NASA; Comiso and Nishio, 2008) and NSIDC; (Fetterer et al., 2002), solid and dashed thick black lines, respectively). The CMIP5 multi-model ensemble mean (thick red line) is based on 37 CMIP5 models (historical simulations extended after 2005 with RCP4.5 projections). Each model is represented with a single simulation. The dotted black line for the Arctic in (a) relates to the pre-satellite period of observation-based time series (Stroeve et al., 2012). In (a) and (b) the panels on the right are based on the corresponding 37-member ensemble means from CMIP5 (thick red lines) and 12-model ensemble means from CMIP3 (thick blue lines). The CMIP3 12-model means are based on CMIP3 historical simulations extended after 1999 with Special Report on Emission Scenarios (SRES) A2 projections. The pink and light blue shadings denote the 5 to 95 percentile range for the corresponding ensembles. Note that these are monthly means, not yearly minima. (Adapted from Pavlova et al., 2011.) (Bottom row) CMIP5 sea ice extent trend distributions over the period 1979–2010 for (c) the Arctic in September and (d) the Antarctic in February. Altogether 66 realizations are shown from 26 different models (historical simulations extended after 2005 with RCP4.5 projections). They are compared against the observations-based estimates of the trends (green vertical lines in (c) and (d) from Comiso and Nishio (2008); blue vertical line in (d) from Parkinson and Cavalieri (2012)). In (c), the observations-based estimates (Cavalieri and Parkinson, 2012; Comiso and Nishio, 2008) coincide.

sea ice components themselves but also in atmospheric circulation. Most CMIP5 models simulate a decrease in Antarctic sea ice extent over the past few decades compared to the small but significant increase observed.

9.4.4 Land Surface, Fluxes and Hydrology

The land surface determines the partitioning of precipitation into evapotranspiration and runoff, and the partitioning of surface net radiation into sensible and latent heat fluxes. Land surface processes therefore impact strongly on both the climate and hydrological resources. This subsection summarizes recent studies on the evaluation of land surface models, wherever possible emphasizing their performance in CMIP3 and CMIP5 climate models.

9.4.4.1 Snow Cover and Near-Surface Permafrost

The modelling of snow and near-surface permafrost (NSP) processes has received increased attention since the AR4, in part because of the recognition that these processes can provide significant feedbacks on climate change (e.g., Koven et al., 2011; Lawrence et al., 2011). The SnowMIP2 project compared results from 33 snowpack models of varying complexity, including some snow models that are used in AOGCMs, using driving data from five NH locations (Rutter et al., 2009). Most snow models were found to be consistent with observations at open sites, but there was much greater discrepancy at forested sites due to the complex interactions between plant canopy and snow cover. Despite these difficulties, the CMIP5 multi-model ensemble reproduces key features of the large-scale snow cover (Figure 9.25). In the NH, models are able to simulate the seasonal cycle of snow cover over the northern parts of continents, with more disagreement in southerly regions where snow cover is sparse, particularly over China and Mongolia (Brutel-Vuilmet et al., 2013). The latter weaknesses are associated with incorrect timing of the snow onset and melt, and possibly with the choice of thresholds for diagnosing snow cover in the model output. In spite of the good performance of the multi-model mean, there is a significant inter-model scatter of spring snow cover extent in some regions. There is a strong linear correlation between Northern-Hemisphere spring snow cover extent and annual mean surface air temperature in the models, consistent with available observations. The recent negative trend in spring snow cover is underestimated by the CMIP5 (and CMIP3) models (Derksen and Brown, 2012), which is associated with an underestimate of the boreal land surface warming (Brutel-Vuilmet et al., 2013).

Some CMIP5 models now represent NSP and frozen soil processes (Koven et al., 2013), but this is not generally the case. Therefore it is difficult to make a direct quantitative evaluation of most CMIP5 models against permafrost observations. A less direct but more inclusive approach is to diagnose NSP extent using snow depths and skin temperatures generated by climate models to drive a stand-alone multi-layer permafrost model (Pavlova et al., 2007). Figure 9.25 shows the result of using this approach on the CMIP5 ensemble. The multi-model mean is able to simulate the approximate location of the NSP boundary (as indicated by the 0°C soil temperature isotherm). However, the range of present-day (1986–2005) NSP area inferred from individual models spans a factor of more than six (~4 to 25 × 10^6 km^2) due

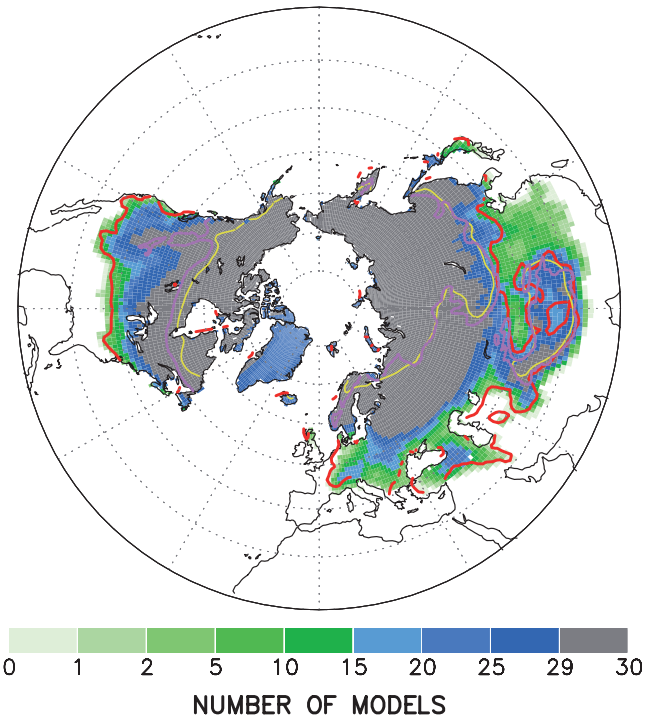

Figure 9.25 | Terrestrial snow cover distribution (1986–2005) in the Northern Hemisphere (NH) as simulated by 30 CMIP5 models for February, updated for CMIP5 from Pavlova et al. (2007). For each 1° × 1° longitude-latitude grid cell, the figure indicates the number of models that simulate at least 5 kg m^{-2} of snow-water equivalent. The observations-based boundaries (red line) mark the territory with at least 20% of the days per month with snow cover (Robinson and Frei, 2000) over the period 1986–2005. The annual mean 0°C isotherm at 3.3 m depth averaged across 24 CMIP5 models (yellow line) is a proxy for the near-surface permafrost boundary. Observed permafrost extent in the NH (magenta line) is based on Brown et al. (1997, 1998).

to differences in simulated surface climate and to varying abilities of the underlying land surface models. Even though many CMIP5 models include some representation of soil freezing in mineral soils, very few include key processes necessary to accurately model NSP changes, such as the distinct properties of organic soils, the existence of local water tables and the heat released by microbial respiration (Nicolsky et al., 2007; Wania et al., 2009; Koven et al., 2011, 2013).

Despite large differences in the absolute NSP area, the relationship between the decrease in NSP area and the warming air temperature over the present-day NSP region is similar, and approximately linear, in many models (Slater and Lawrence, 2013).

9.4.4.2 Soil Moisture and Surface Hydrology

The partitioning of precipitation into evapotranspiration and runoff is highly dependent on the moisture status of the land surface, especially the amount of soil moisture available for evapotranspiration, which in turn depends on properties of the land cover such as the rooting depth of plants.

There has been a long history of off-line evaluation of land surface schemes, aided more recently by the increasing availability of site-specific data (Friend et al., 2007; Blyth et al., 2010). Throughout this time,

representations of the land surface have significantly increased in complexity, allowing the representation of key processes such as links between stomatal conductance and photosynthesis, but at the cost of increasing the number of poorly known internal model parameters. These more sophisticated land surface models are based on physical principles that should make them more appropriate for projections of future climate and increased CO_2. However for specific data-rich sites, current land surface models still struggle to perform as well as statistical models in predicting year-to-year variations in latent and sensible heat fluxes (Abramowitz et al., 2008) and runoff (Materia et al., 2010).

There are few evaluations of the performance of land surface schemes in coupled climate models, but those that have been undertaken find major limitations associated with the atmospheric forcing rather than the land surface schemes themselves. For example, an evaluation of the soil moisture simulations of CMIP3 models found that long-term soil moisture trends could only be reproduced in models that simulated the reduction in solar radiation at the surface associated with 'global dimming' (Li et al., 2007). A comparison of simulated evapotranspiration fluxes from CMIP3 against large-scale observation-based estimates, showed underestimates in India and parts of eastern South America, and overestimates in the western USA, Australia and China (Mueller et al., 2011).

Land–atmosphere coupling determines the ability of climate models to simulate the influence of soil moisture anomalies on rainfall, droughts and high-temperature extremes (Fischer et al., 2007; Lorenz et al., 2012). The coupling strength depends both on the sensitivity of evapotranspiration to soil moisture, which is determined by the land surface scheme, and the sensitivity of precipitation to evapotranspiration, which is determined by the atmospheric model (Koster et al., 2004; Seneviratne et al., 2010). Comparison of climate model simulations to observations suggests that the models correctly represent the soil-moisture impacts on temperature extremes in southeastern Europe, but overestimate them in central Europe (Hirschi et al., 2011). The influence of soil moisture on rainfall varies significantly with region, and with the lead-time between a soil moisture anomaly and a rainfall event (Seneviratne et al., 2010). In some regions, such as the Sahel, enhanced precipitation can even be induced by dry anomalies (Taylor et al., 2011). Recent analyses of CMIP5 models reveals considerable spread in the ability of the models to reproduce observed correlations between precipitation and soil moisture in the tropics (Williams et al., 2012), and a systematic failure to simulate the positive impact of dry soil moisture anomalies on rainfall in the Sahel (Taylor et al., 2012a).

9.4.4.3 Dynamic Global Vegetation and Nitrogen Cycling

At the time of the AR4 very few climate models included dynamic vegetation, with vegetation being prescribed and fixed in all but a handful of coupled climate–carbon cycle models (Friedlingstein et al., 2006). Dynamic Global Vegetation Models (DGVMs) certainly existed at the time of the AR4 (Cramer et al., 2001) but these were not typically incorporated in climate models. Since the AR4 there has been continual development of offline DGVMs, and some climate models incorporate dynamic vegetation in at least a subset of the runs submitted to CMIP5 (also see Section 9.1.3.2.4), with likely consequences for climate model biases and regional climate projection (Martin and Levine, 2012).

DGVMs are designed to simulate the large-scale geographical distribution of plant functional types and how these patterns will change in response to climate change, CO_2 increases, and other forcing factors (Cramer et al., 2001). These models typically include rather detailed representations of plant photosynthesis but less sophisticated treatments of soil carbon, with a varying number of soil carbon pools. In the absence of nitrogen limitations on CO_2 fertilization, offline DGVMs agree qualitatively that CO_2 increase alone will tend to enhance carbon uptake on the land while the associated climate change will tend to reduce it. There is also good agreement on the degree of CO_2 fertilization in the case of no nutrient limitation (Sitch et al., 2008). However, under more extreme emissions scenarios the responses of the DGVMs diverge markedly. Large uncertainties are associated with the responses of tropical and boreal ecosystems to elevated temperatures and changing soil moisture status. Particular areas of uncertainty are the high-temperature response of photosynthesis (Galbraith et al., 2010), and the extent of CO_2 fertilization (Rammig et al., 2010) in the Amazonian rainforest.

Most of the land surface models and DGVMs used in the CMIP5 models continue to neglect nutrient limitations on plant growth (see Section 6.4.6.2), even though these may significantly moderate the response of photosynthesis to CO_2 (Wang and Houlton, 2009). Recent extensions of two land surface models to include nitrogen limitations improve the fit to 'Free-Air CO_2 Enrichment Experiments', and suggest that models without these limitations are expected to overestimate the land carbon sink in the nitrogen-limited mid and high latitudes (Thornton et al., 2007; Zaehle et al., 2010).

9.4.4.4 Land Use Change

A major innovation in the land component of ESMs since the AR4 is the inclusion of the effects of land use change associated with the spread of agriculture, urbanization and deforestation. These affect climate by altering the biophysical properties of the land surface, such as its albedo, aerodynamic roughness and water-holding capacity (Bondeau et al., 2007; Bonan, 2008; Bathiany et al., 2010; Levis, 2010). Land use change has also contributed almost 30% of total anthropogenic CO_2 emissions since 1850 (see Table 6.1), and affects emissions of trace gases, and VOCs such as isoprene. The latest ESMs used in CMIP5 attempt to model the CO_2 emissions implied by prescribed land use change and many also simulate the associated changes in the biophysical properties of the land surface. This represents a major advance on the CMIP3 models which typically neglected land use change, aside from its assumed contribution to anthropogenic CO_2 emissions.

However, the increasing sophistication of the modelling of the impacts of land use change has introduced additional spread in climate model projections. The first systematic model intercomparison demonstrated that large-scale land cover change can significantly affect regional climate (Pitman et al., 2009) and showed a large spread in the response of different models to the same imposed land cover change (de Noblet-Ducoudre et al., 2012). This uncertainty arises from the often counteracting effects of evapotranspiration and albedo changes (Boisier et al., 2012) and has consequences for the simulation of temperature and rainfall extremes (Pitman et al., 2012b).

9.4.5 Carbon Cycle

An important development since the AR4 is the more widespread implementation of ESMs that include an interactive carbon cycle. Coupled climate-carbon cycle models are used extensively for the projections presented in Chapter 12. The evaluation of the carbon cycle within coupled models is discussed here, while the performance of the individual land and ocean carbon models, together with the detailed analysis of climate–carbon cycle feedbacks, is presented in Chapter 6 (Section 6.4 and Box 6.4).

The transition from AOGCMs to ESMs was motivated in part by the results from the first generation coupled climate–carbon cycle models, which suggested that feedbacks between the climate and the carbon cycle were uncertain but potentially very important in the context of 21st century climate change (Cox et al., 2000; Friedlingstein et al., 2001). The first-generation models used in the Coupled Climate Carbon Cycle Model Intercomparison Project (C^{4}MIP) included both extended AOGCMS and EMICs. The C^{4}MIP experimental design involved running each model under a common emission scenario (SRES A2) and calculating the evolution of the global atmospheric CO_2 concentration interactively within the model. The impacts of climate–carbon cycle feedbacks were diagnosed by carrying out parallel "uncoupled" simulations in which increases in atmospheric CO_2 did not influence climate. Analysis of the C^{4}MIP runs highlighted a greater than 200 ppmv range in the CO_2 concentration by 2100 due to uncertainties in climate–carbon cycle feedbacks, and that the largest uncertainties were associated with the response of land ecosystems to climate and CO_2 (Friedlingstein et al., 2006).

For CMIP5 a different experimental design was proposed in which the core simulations use prescribed RCPs of atmospheric CO_2 and other GHGs (Moss et al., 2010). Under a prescribed CO_2 scenario, ESMs calculate land and ocean carbon fluxes interactively, but these fluxes do not affect the evolution of atmospheric CO_2. Instead the modelled land and ocean fluxes, along with the prescribed increase in atmospheric CO_2, can be used to diagnose the 'compatible' emissions of CO_2 consistent with the simulation (see Section 6.3; Miyama and Kawamiya, 2009; Arora et al., 2011). The compatible emissions for each model can then be evaluated against the best estimates of the actual historical CO_2 emissions. Parallel model experiments in which the carbon cycle does not respond to the simulated climate change (which are equivalent to the 'uncoupled' simulations in C^{4}MIP) provide a means to diagnose climate–carbon cycle feedbacks in terms of their impact on the compatible emissions of CO_2 (Hibbard et al., 2007).

Carbon cycle model evaluation is limited by the availability of direct observations at appropriately large spatial scales. Field studies and eddy-covariance flux measurements provide detailed information on the land carbon cycle over short-time scales and for specific locations, and ocean inventories are able to constrain the long-term uptake of anthropogenic CO_2 by the ocean (Sabine et al., 2004; Takahashi et al., 2009). However the stores of carbon on the land are less well-known, even though these are important determinants of the CO_2 fluxes from land use change. ESM simulations vary by a factor of at least six in global soil carbon (Anav et al., 2013; Todd-Brown et al., 2013) and by a factor of four in global vegetation carbon, although about two thirds of models are within 50% of the uncertain observational estimates (Anav et al., 2013).

Large-scale land–atmosphere and global atmosphere fluxes are not directly measured, but global estimates can be made from the carbon balance, and large-scale regional fluxes can be estimated from the inversion of atmospheric CO_2 measurements (see Section 6.3.2). Figure 9.26 shows modelled annual mean ocean–atmosphere and net land–atmosphere CO_2 fluxes from the historical simulations in the CMIP5 archive (Anav et al., 2013). Also shown are estimates derived from offline ocean carbon cycle models, measurements of atmospheric CO_2, and best estimates of the CO_2 fluxes from fossil fuels and land use change (Le Quere et al., 2009). Uncertainties in these latter annual estimates are approximately ±0.5 PgC yr^{-1}, arising predominantly from the uncertainty in the model-derived ocean CO_2 uptake. The confidence limits for the ensemble mean are derived by assuming that the CMIP5 models form a *t*-distribution centred on the ensemble mean (Anav et al., 2013).

The evolution of the global ocean carbon sink is shown in the top panel of Figure 9.26. The CMIP5 ensemble mean global ocean uptake (± standard deviation of the multi-model ensemble), computed using all the 23 models that reported ocean CO_2 fluxes, increases from 0.47 ± 0.32 PgC yr^{-1} over the period 1901–1930 to 1.53 ± 0.36 PgC yr^{-1} for the period 1960–2005. For comparison, the Global Carbon Project (GCP) estimates a stronger ocean carbon sink of 1.92 ± 0.3 PgC yr^{-1} for 1960–2005 (Anav et al., 2013). The bottom panel of Figure 9.26 shows the variability in global land carbon uptake evident in the GCP estimates, with the global land carbon sink being strongest during La Niña years and after volcanoes, and turning into a source during El Niño years. The CMIP5 models cannot be expected to precisely reproduce this year-to-year variability as these models will naturally simulate chaotic ENSO variability that is out of phase with the historical variability. However, the ensemble mean does successfully simulate a strengthening global land carbon sink during the 1990s, especially after the Mt Pinatubo eruption in 1991. The CMIP5 ensemble mean land–atmosphere flux (± standard deviation of the multi-model ensemble) evolves from a small source of –0.34 ± 0.49 PgC yr^{-1} over the period 1901–1930, predominantly due to land use change, to a sink of 0.47 ± 0.72 PgC yr^{-1} in the period 1960–2005. The GCP estimates give a weaker sink of 0.36 ± 1 PgC yr^{-1} for the 1960–2005 period.

Figure 9.27 shows the ocean–atmosphere fluxes (top panel) and mean land–atmosphere fluxes (bottom panel) simulated by ESMs and EMICs (Eby et al., 2013) for the period 1986–2005, and compares these to observation-based estimates from GCP and Atmospheric Tracer Transport Model Intercomparison Project (TRANSCOM3) atmospheric inversions (Gurney et al., 2003). Unlike Figure 9.26, only models that reported both land and ocean carbon fluxes are included in this figure. The atmospheric inversions results are taken from the Japanese Meteorological Agency (JMA) as this was the only TRANSCOM3 model that reported results for all years of the 1986–2005 reference period. The error bars on the observational estimates (red triangles) and the ESM simulations (black diamonds) represent the interannual variation in the form of the standard deviation of the annual fluxes. EMICs do not typically simulate interannual variability, so only mean values are shown for these models (green boxes). Here, as in Figure 9.26, the net

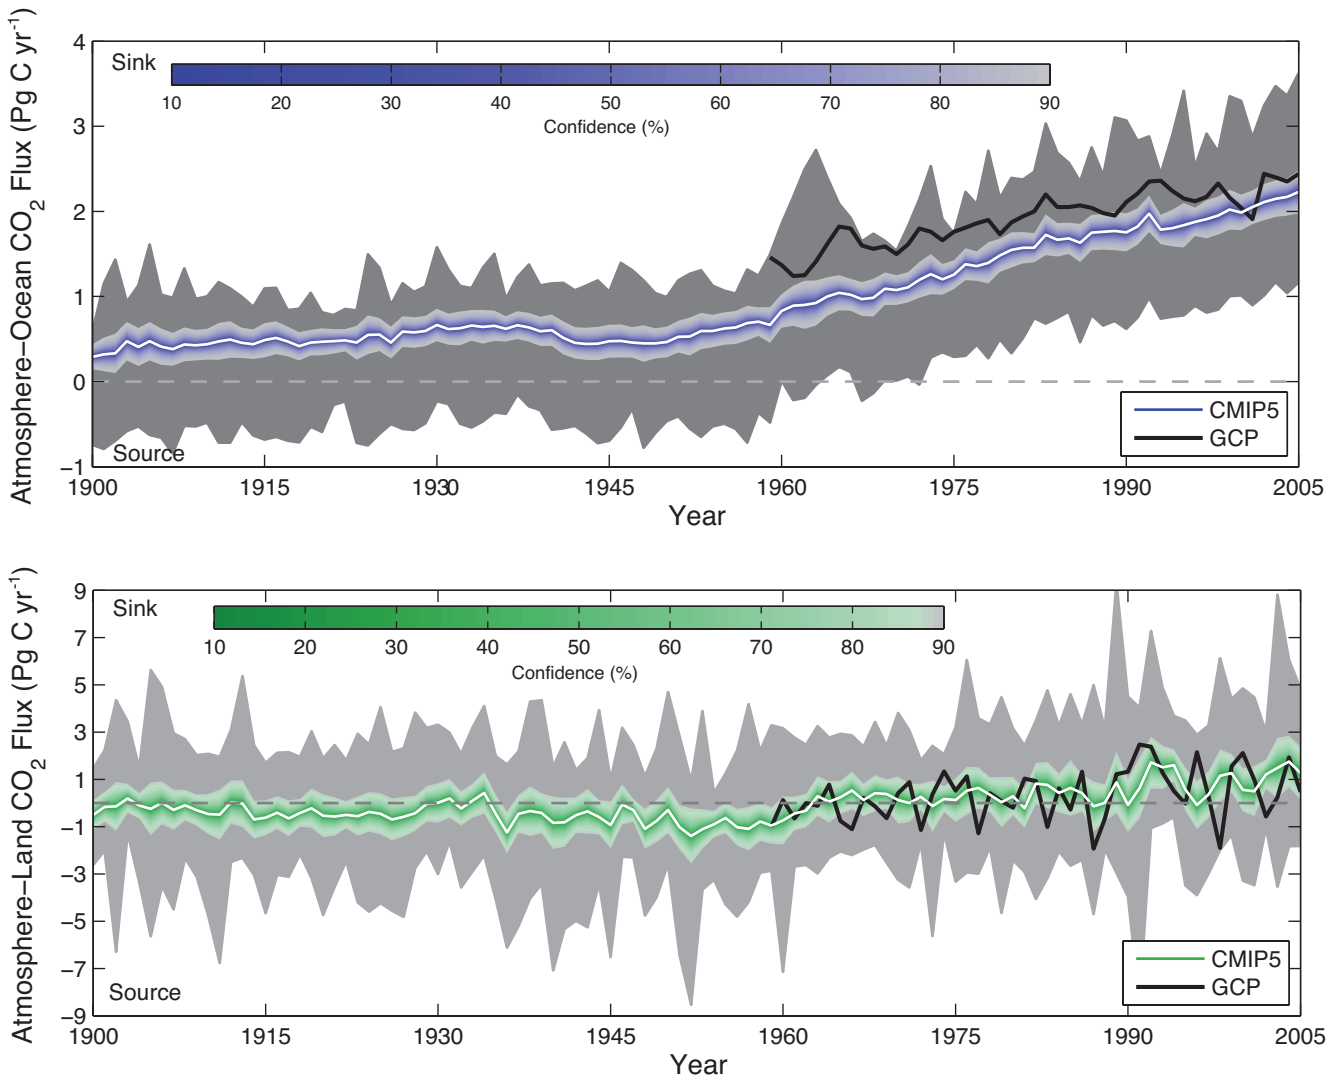

Figure 9.26 | Ensemble-mean global ocean carbon uptake (top) and global land carbon uptake (bottom) in the CMIP5 ESMs for the historical period 1900–2005. For comparison, the observation-based estimates provided by the Global Carbon Project (Le Quere et al., 2009) are also shown (thick black line). The confidence limits on the ensemble mean are derived by assuming that the CMIP5 models come from a *t*-distribution. The grey areas show the range of annual mean fluxes simulated across the model ensemble. This figure includes results from all CMIP5 models that reported land CO_2 fluxes, ocean CO_2 fluxes, or both (Anav et al., 2013).

land–atmosphere flux is 'Net Biome Productivity (NBP)' which includes the net CO_2 emissions from land use change as well as the changing carbon balance of undisturbed ecosystems.

For the period 1986–2005 the observation-based estimates of the global ocean carbon sink are 1.71 PgC yr^{-1} (JMA), 2.19 PgC yr^{-1} (GCP) and 2.33 PgC yr^{-1} (Takahashi et al., 2009). Taking into account the uncertainties in the mean values of these fluxes associated with interannual variability, the observationally constrained range is approximately 1.4 to 2.4 PgC yr^{-1}. All of the ESMs, and all but one of the EMICs, simulate ocean sinks within this range. The observation-based estimates of GCP and JMA agree well on the mean global land carbon sink over the period 1986–2005, and most ESMs fit within the uncertainty bounds of these estimates (i.e., 1.17 ± 1.06 PgC yr^{-1} for JMA). The exceptions are two ESMs sharing common atmosphere and land components (CESM1-BGC and NorESM1-ME) which model a net land carbon source rather than a sink over this period. The EMICs tend to systematically underestimate the contemporary land carbon sink (Eby et al., 2013). Some ESMs (notably GFDL-ESM2M and GFDL-ESM2G) significantly overestimate the interannual variation in the global land–atmosphere CO_2 flux, with a possible consequence being an overestimate of the vulnerability of tropical ecosystems to future climate change (Cox et al., 2013), and see Figure 9.45). All ESMs qualitatively simulate the expected pattern of ocean CO_2 fluxes, with outgassing in the tropics and uptake in the mid and high latitudes (Anav et al., 2013). However, there are systematic differences between the ESMs and the JMA inversion estimates for the zonal land CO_2 fluxes, with the ESMs tending to produce weaker uptake in the NH, and simulating a net land carbon sink rather than a source in the tropics.

In summary, there is *high confidence* that CMIP5 ESMs can simulate the global mean land and ocean carbon sinks within the range of observation-based estimates. Overall, EMICs reproduce the recent global ocean CO_2 fluxes uptake as well as ESMs, but estimate a lower

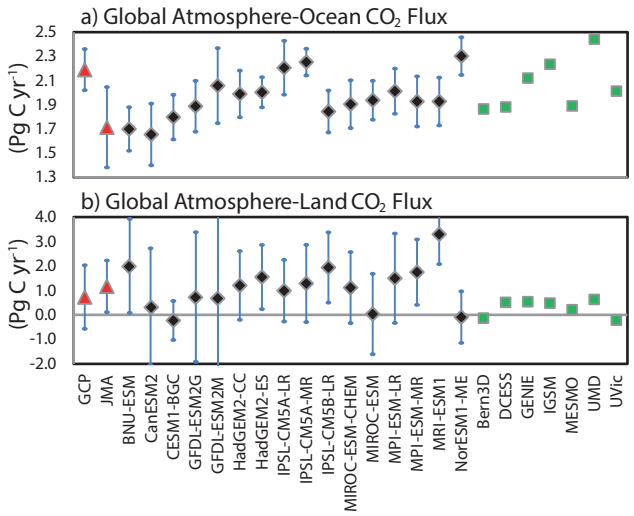

Figure 9.27 | Simulation of global mean (a) atmosphere–ocean CO_2 fluxes ('fgCO2') and (b) net atmosphere–land CO_2 fluxes ('NBP'), by ESMs (black diamonds) and EMICs (green boxes), for the period 1986–2005. For comparison, the observation-based estimates provided by Global Carbon Project (GCP; Le Quere et al., 2009), and the Japanese Meteorological Agency (JMA) atmospheric inversion (Gurney et al., 2003) are also shown as the red triangles. The error bars for the ESMs and observations represent interannual variability in the fluxes, calculated as the standard deviation of the annual means over the period 1986–2005.

land carbon sink compared with most ESMs while remaining consistent with the observations (Eby et al., 2013). With few exceptions, the CMIP5 ESMs also reproduce the large-scale pattern of ocean–atmosphere CO_2 fluxes, with uptake in the Southern Ocean and northern mid-latitudes, and outgassing in the tropics. However, the geographical pattern of simulated land–atmosphere fluxes agrees much less well with inversion estimates, which suggest a larger sink in the northern mid-latitudes, and a net source rather than a sink in the tropics. While there are also inherent uncertainties in atmospheric inversions, discrepancies like this might be expected from known deficiencies in the CMIP5 generation of ESMs—namely the failure to correctly simulate nitrogen fertilization in the mid-latitudes, and a rudimentary treatment of the net CO_2 emissions arising from land use change and forest regrowth.

9.4.6 Aerosol Burdens and Effects on Insolation

9.4.6.1 Recent Trends in Global Aerosol Burdens and Effects on Insolation

The ability of CMIP5 models to simulate the current burden of tropospheric aerosol and the decadal trends in this burden can be assessed using observations of aerosol optical depth (AOD, see Section 7.3.1.2). The historical data used to drive the CMIP5 20th century simulations reflect recent trends in anthropogenic SO_2 emissions, and hence these trends should be manifested in the modelled and observed AOD. During the last three decades, anthropogenic emissions of SO_2 from North America and Europe have declined due to the imposition of emission controls, while the emissions from Asia have increased. The combination of the European, North American, and Asians trends has yielded a global reduction in SO_2 emissions of 20 Gg(SO_2), or 15% between 1970 and 2000 although emissions subsequently increased by 9 Gg(SO_2) between 2000 and 2005 (Smith et al., 2011b). For the period 2001 to 2005, CMIP5 models underestimate the mean AOD at 550 nm relative to satellite-retrieved AOD by at least 20% over virtually all land surfaces (Figure 9.28). The differences between the modelled and measured AODs exceed the errors in the Multi-angle Imaging Spectro-Radiometer (MISR) retrievals over land of ±0.05 or 0.2×AOD (Kahn et al., 2005) and the RMS errors in the corrected Moderate Resolution Imaging Spectrometer (MODIS) retrievals over ocean of 0.061(Shi et al., 2011).

The effects of sulphate and other aerosol species on surface insolation through direct and indirect forcing appear to be one of the principal causes of the 'global dimming' between the 1960s and 1980s and subsequent 'global brightening' in the last two decades (see Section 2.3.3.1). This inference is supported by trends in aerosol optical depth and trends in surface insolation under cloud-free conditions. Thirteen out of 14 CMIP3 models examined by Ruckstuhl and Norris (2009) produce a transition from "dimming" to 'brightening' that is consistent with the timing of the transition from increasing to decreasing global anthropogenic aerosol emissions. The transition from 'dimming' to 'brightening' in both Europe and North America is well simulated with the HadGEM2 model (Haywood et al., 2011).

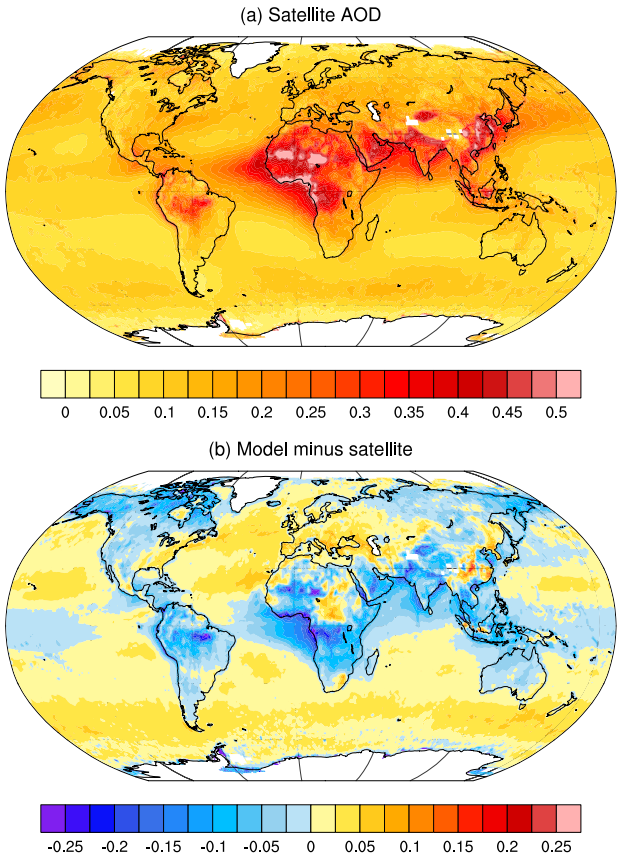

Figure 9.28 | (a): Annual mean visible aerosol optical depth (AOD) for 2001 through 2005 using the Moderate Resolution Imaging Spectrometer (MODIS) version 5 satellite retrievals for ocean regions (Remer et al., 2008) with corrections (Zhang et al., 2008a; Shi et al., 2011) and version 31 of MISR retrievals over land (Zhang and Reid, 2010; Stevens and Schwartz, 2012). (b): The absolute error in visible AOD from the median of a subset of CMIP5 models' historical simulations relative to the satellite retrievals of AOD shown in (a). The model outputs for 2001 through 2005 are from 21 CMIP5 models with interactive or semi-interactive aerosol representation.

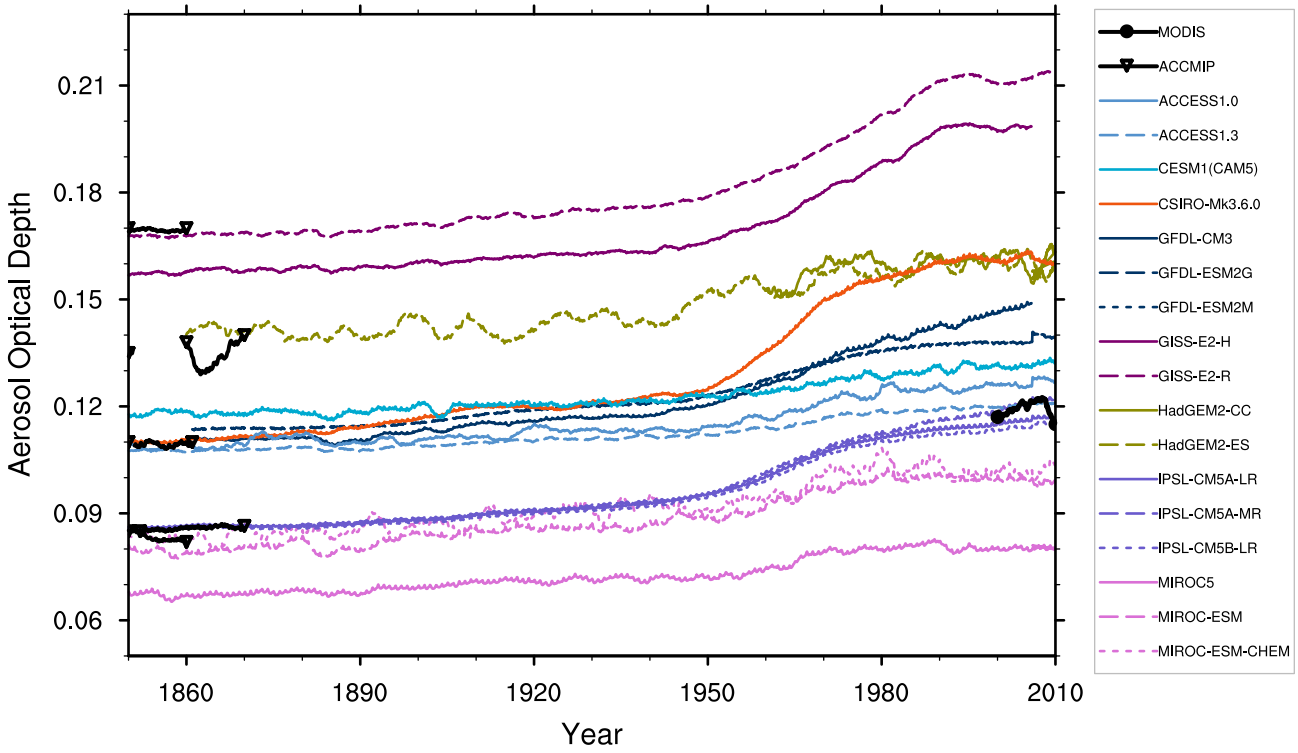

Figure 9.29 | Time series of global oceanic mean aerosol optical depth (AOD) from individual CMIP5 models' historical (1850–2005) and RCP4.5 (2006–2010) simulations, corrected Moderate Resolution Imaging Spectrometer (MODIS) satellite observations by Shi et al. (2011) and Zhang et al. (2008a), and the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) simulations for the 1850s by Shindell et al. (2013b).

These recent trends are superimposed on a general upward trend in aerosol loading since 1850 reflected by an increase in global mean oceanic AODs from the CMIP5 historical and RCP 4.5 simulations from 1850 to 2010 (Figure 9.29). Despite the use of common anthropogenic aerosol emissions for the historical simulations (Lamarque et al., 2010), the simulated oceanic AODs for 2010 range from 0.08 to 0.215, with nearly equal numbers of models over and underestimating the satellite retrieved AOD of 0.12 (Figure 9.29). This range in AODs results from differing estimates of the trends and of the initial global mean oceanic AOD at 1850 across the CMIP5 ensemble (Figure 9.29).

9.4.6.2 Principal Sources of Uncertainty in Projections of Sulphate Burdens

Natural sources of sulphate from oxidation of dimethylsulphide (DMS) emissions from the ocean surface are not specified under the RCP protocol and therefore represent a source of uncertainty in the sulphur cycle simulated by the CMIP5 ensemble. In simulations of present-day conditions, DMS emissions span a 5 to 95% confidence interval of 10.7 to 28.1 TgS yr^{-1} (Faloona, 2009). After chemical processing, DMS contributes between 18 and 42% of the global atmospheric sulphate burden and up to 80% of the sulphate burden over most of the SH (Carslaw et al., 2010). Several CMIP5 models include prognostic calculation of the biogenic DMS source; however, the effects from differences in DMS emissions on modelled sulphate burdens remain to be quantified.

In contrast to CMIP3, the models in the CMIP5 ensemble are provided with a single internally consistent set of future anthropogenic SO_2 emissions. The use of a single set of emissions removes an important, but not dominant, source of uncertainty in the AR5 simulations of the sulphur cycle. In experiments based on a single chemistry–climate model with perturbations to both emissions and sulphur-cycle processes, uncertainties in emissions accounted for 53.3% of the ensemble variance (Ackerley et al., 2009). The next largest source of uncertainty was associated with the wet scavenging of sulphate (see Section 7.3.2), which accounted for 29.5% of the intra-ensemble variance and represents the source/sink term with the largest relative range in the aerosol models evaluated by Faloona (2009). Similarly, simulations run with heterogeneous or harmonized emissions data sets yielded approximately the same intermodel standard deviation in sulphate burden of 25 Tg. These results show that a dominant source of the spread among the sulphate burdens is associated with differences in the treatment of chemical production, transport, and removal from the atmosphere (Liu et al., 2007; Textor et al., 2007). Errors in modelled aerosol burden systematically affect anthropogenic RF (Shindell et al., 2013b).

9.5 Simulation of Variability and Extremes

9.5.1 Importance of Simulating Climate Variability

The ability of a model to simulate the mean climate, and the slow, externally forced change in that mean state, was evaluated in the previous section. However, the ability to simulate climate variability, both unforced internal variability and forced variability (e.g., diurnal and seasonal cycles) is also important. This has implications for the signal-

to-noise estimates inherent in climate change detection and attribution studies where low-frequency climate variability must be estimated, at least in part, from long control integrations of climate models (Section 10.2). It also has implications for the ability of models to make quantitative projections of changes in climate variability and the statistics of extreme events under a warming climate. In many cases, the impacts of climate change will be experienced more profoundly in terms of the frequency, intensity or duration of extreme events (e.g., heat waves, droughts, extreme rainfall events; see Section 12.4). The ability to simulate climate variability is also central to achieving skill in climate prediction by initializing models from the observed climate state (Sections 11.1 and 11.2).

Evaluating model simulations of climate variability also provides a means to explore the representation of certain processes, such as the coupled processes underlying the ENSO and other important modes of variability. A model's representation of the diurnal or seasonal cycle—both of which represent responses to external (rotational or orbital) forcing – may also provide some insight into a model's 'sensitivity' and by extension, the ability to respond correctly to GHG, aerosol, volcanic and solar forcing.

9.5.2 Diurnal-to-Seasonal Variability

9.5.2.1 Diurnal Cycles of Temperature and Precipitation

The diurnally varying solar radiation received at a given location drives, through complex interactions with the atmosphere, land surface and upper ocean, easily observable diurnal variations in surface and near-surface temperature, precipitation, level stability and winds. The AR4 noted that climate models simulated the global pattern of the diurnal temperature range, zonally and annually averaged over the continent, but tended to underestimate its magnitude in many regions (Randall et al., 2007). New analyses over land indicate that model deficiencies in surface–atmosphere interactions and the planetary boundary layer are also expected to contribute to some of the diurnal cycle errors and that model agreement with observations depends on region, vegetation type and season (Lindvall et al., 2012). Analyses of CMIP3 simulations show that the diurnal amplitude of precipitation is realistic, but most models tend to start moist convection prematurely over land (Dai, 2006; Wang et al., 2011a). Many CMIP5 models also have peak precipitation several hours too early compared to surface observations and TRMM satellite observations (Figure 9.30). This and the so-called 'drizzling bias' (Dai, 2006) can have large adverse impacts on surface evaporation and runoff (Qian et al., 2006). Over the ocean, models often rain too frequently and underestimated the diurnal amplitude (Stephens et al., 2010). It has also been suggested that a weak diurnal cycle of surface air temperature is produced over the ocean because of a lack of diurnal variations in SST (Bernie et al., 2008), and most models have difficulty with this due to coarse vertical resolution and coupling frequency (Dai and Trenberth, 2004; Danabasoglu et al., 2006).

Improved representation of the diurnal cycle has been found with increased atmospheric resolution (Sato et al., 2009; Ploshay and Lau, 2010) or with improved representation of cloud physics (Khairoutdinov et al., 2005), but the reasons for these improvements remain poorly understood. Other changes such as the representation of entrainment in deep convection (Stratton and Stirling, 2012), improved coupling between shallow and deep convection, and inclusion of density currents (Peterson et al., 2009) have been shown to greatly improve the diurnal cycle of convection over tropical land and provide a good representation of the timing of convection over land in coupled ocean–atmosphere simulations (Hourdin et al., 2013). Thanks to improvements like this, the best performing models in Figure 9.30 appear now to be able to capture the land and ocean diurnal phase and amplitude quite well.

9.5.2.2 Blocking

In the mid latitudes, climate is often characterized by weather regimes (see Chapter 2), amongst which blocking regimes play a role in the occurrence of extreme weather events (Buehler et al., 2011; Sillmann et al., 2011; Pfahl and Wernli, 2012). During blocking, the prevailing mid-latitude westerly winds and storm systems are interrupted by a local reversal of the zonal flow. Climate models in the past have universally underestimated the occurrence of blocking, in particular in the Euro-Atlantic sector (Scaife et al., 2010).

There are important differences in methods used to identify blocking (Barriopedro et al., 2010a), and the diagnosed blocking frequency can be very sensitive to details such as the choice of latitude (Barnes et al., 2012). Blocking indices can be sensitive to biases in the representation of mean state (Scaife et al., 2010) or in variability (Barriopedro et al., 2010b; Vial and Osborn, 2012). When blocking is measured via anomaly fields, rather than reversed absolute fields, model skill can be high even in relatively low-resolution models (e.g., Sillmann and Croci-Maspoli, 2009).

Recent work has shown that models with high horizontal (Matsueda, 2009; Matsueda et al., 2009, 2010) or vertical resolution (Anstey et al., 2013) are better able to simulate blocking. These improvement arise from increased representation of orography and atmospheric dynamics (Woollings et al., 2010b; Jung et al., 2012; Berckmans et al., 2013), as well as reduced ocean surface temperature errors in the extra tropics (Scaife et al., 2011). Improved physical parameterizations have also been shown to improve simulations of blocking (Jung et al., 2010). However, as in CMIP3 (Scaife et al., 2010; Barnes et al., 2012), most of the CMIP5 models still significantly underestimate winter Euro-Atlantic blocking (Anstey et al., 2013; Masato et al., 2012; Dunn-Sigouin and Son, 2013). These new results show that the representation of blocking events is improving in models, even though the overall quality of CMIP5 ensemble is medium. There is *high confidence* that model representation of blocking is improved through increases in model resolution.

9.5.2.3 Madden–Julian Oscillation

During the boreal winter the eastward propagating feature known as the Madden–Julian Oscillation (MJO; (Madden and Julian, 1972, 1994) predominantly affects the deep tropics, while during the boreal summer there is also northward propagation over much of southern Asia (Annamalai and Sperber, 2005). The MJO has received much attention given the prominent role it plays in tropical climate variability (e.g., monsoons, ENSO, and mid-latitudes; Lau and Waliser, 2011)

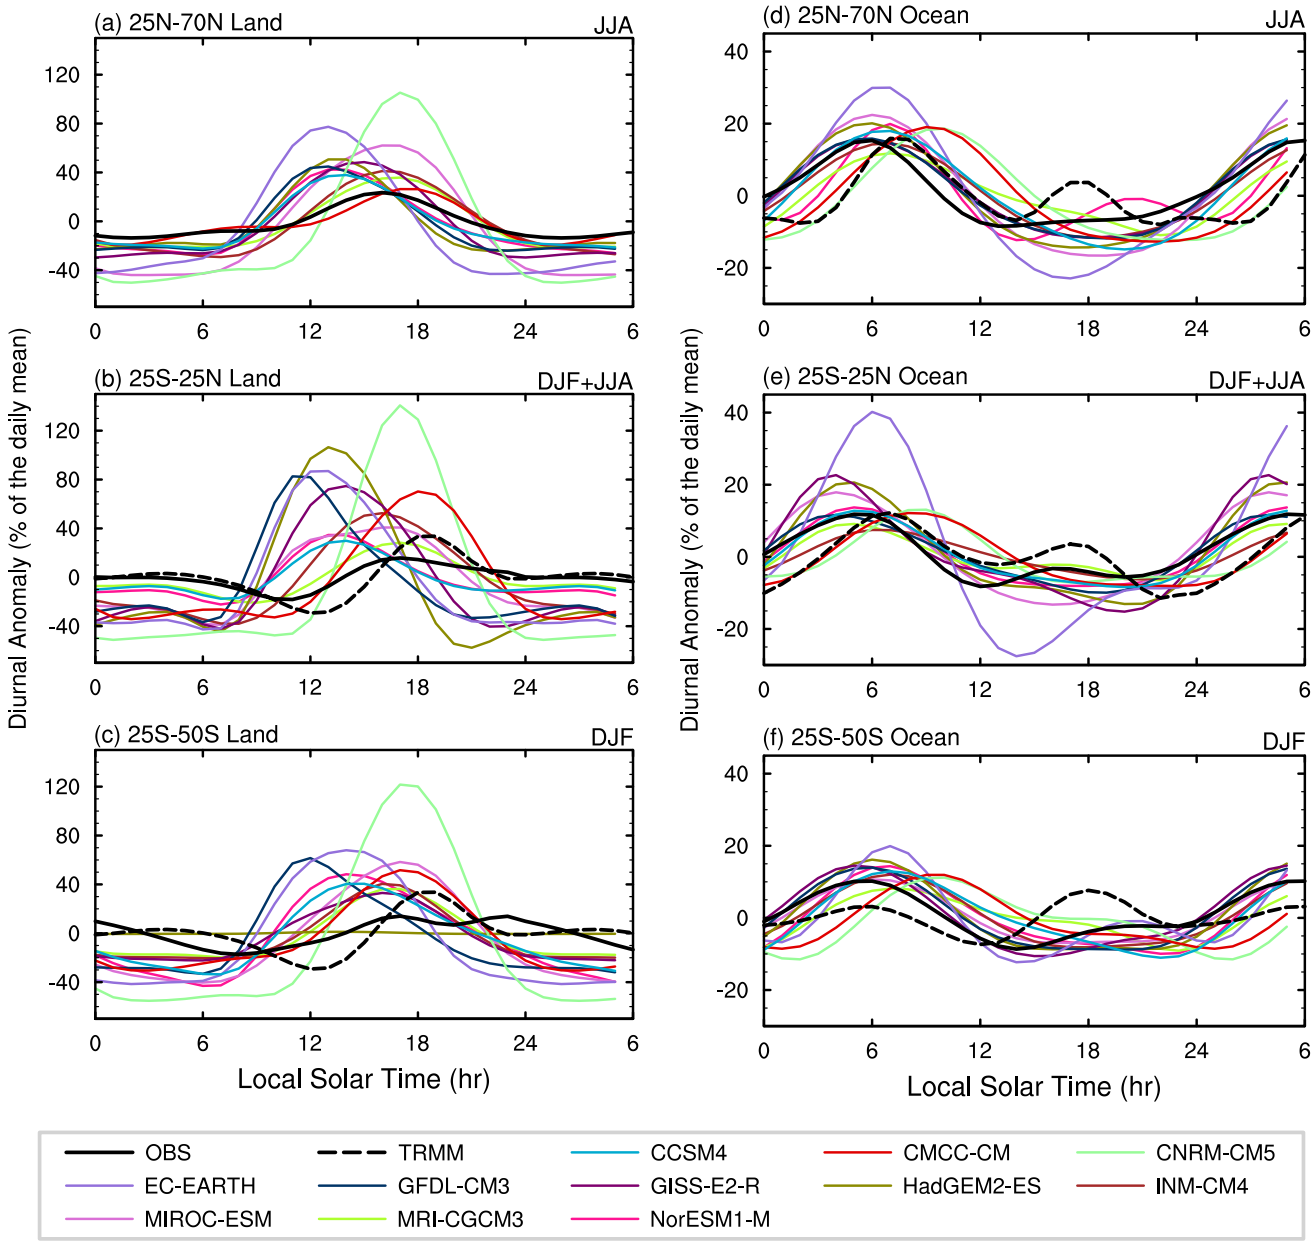

Figure 9.30 | Composite diurnal cycle of precipitation averaged over land (left) and ocean (right) for three different latitude bands at each local time and season (June–July–August (JJA), December–January–February (DJF), or their sum). For most of the CMIP5 models, data from 1980–2005 from the historical runs were averaged to derived the composite cycle; however, a few models had the required 3-hourly data only for 1990–2005 or 1996–2005. For comparison with the model results, a similar diagnosis from observations are shown (black solid line: surface-observed precipitation frequency; black dashed line: TRMM 3B42 data set, 1998–2003 mean). (Update of Figure 17 of Dai, 2006.)

Phenomenological diagnostics (Waliser et al., 2009a) and process-oriented diagnostics (e.g., Xavier, 2012) have been used to evaluate MJO in climate models. An important reason for model errors in representing the MJO is that convection parameterizations do not provide sufficient build-up of moisture in the atmosphere for the large scale organized convection to occur (Kim et al., 2012; Mizuta et al., 2012). Biases in the model mean state also contribute to poor MJO simulation (Inness et al., 2003). High-frequency coupling with the ocean is also an important factor (Bernie et al., 2008). While new parameterizations of convection may improve the MJO (Hourdin et al., 2013), this sometimes occurs at the expense of a good simulation of the mean tropical climate (Kim et al., 2012). In addition, high resolution models with an improved diurnal cycle do not necessarily produce an improved MJO (Mizuta et al., 2012).

Most models underestimate the strength and the coherence of convection and wind variability (Lin et al., 2006; Lin and Li, 2008). The simplified metric shown in Figure 9.31 provides a synthesis of CMIP3 and CMIP5 model results (Sperber and Kim, 2012). It shows that simulation of the MJO is still a challenge for climate models (Lin et al., 2006; Kim et al., 2009; Xavier et al., 2010). Most models have weak coherence in their MJO propagation (smaller maximum positive correlation). Even so, relative to CMIP3 there has been improvement in CMIP5 in simulating the eastward propagation of boreal winter MJO convection from

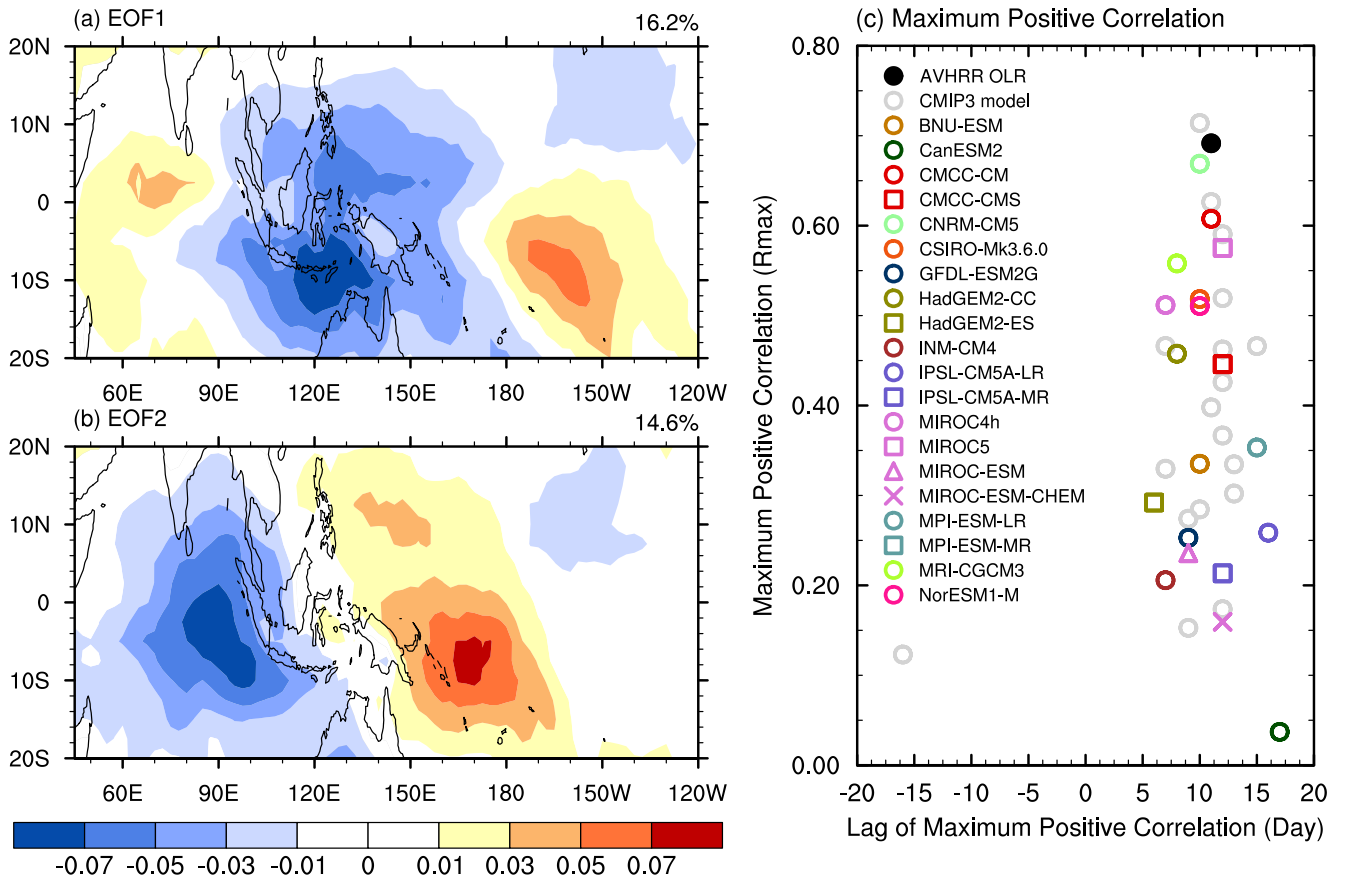

Figure 9.31 | (a, b) The two leading Empirical Orthogonal Functions (EOFs) of outgoing longwave radiation (OLR) from years of strong Madden–Julian Oscillation (MJO) variability computed following Sperber (2003). The 20- to 100-day filtered OLR from observations and each of the CMIP5 historical simulations and the CMIP3 simulations of 20th century climate is projected on these two leading EOFs to obtain MJO Principal Component time series. The scatterplot (c) shows the maximum positive correlation between the resulting MJO Principal Components and the time lag at which it occurred for all winters (November to March). The maximum positive correlation is an indication of the coherence with which the MJO convection propagates from the Indian Ocean to the Maritime Continent/western Pacific, and the time lag is approximately one fourth of the period of the MJO. (Constructed following Sperber and Kim, 2012.)

the Indian Ocean into the western Pacific (Hung et al., 2013) and northward propagation during boreal summer (Sperber et al., 2012). In addition there is evidence that models reproduce MJO characteristics in the east Pacific (Jiang et al., 2012b), and that, overall, there is improvement compared to previous generations of climate models (Waliser et al., 2003; Lin et al., 2006; Sperber and Annamalai, 2008).

9.5.2.4 Large-Scale Monsoon Rainfall and Circulation

Monsoons are the dominant modes of annual variation in the tropics (Trenberth et al., 2000; Wang and Ding, 2008), and affect weather and climate in numerous regions (Chapter 14). High-fidelity simulation of the mean monsoon and its variability is of great importance for simulating future climate impacts (Wang, 2006; Sperber et al., 2010; Colman et al., 2011; Turner and Annamalai, 2012). The monsoon is characterized by an annual reversal of the low level winds and well defined dry and wet seasons (Wang and Ding, 2008), and its variability is primarily connected to the MJO and ENSO (Section 9.5.3). The AR4 reported that most CMIP3 models poorly represent the characteristics of the monsoon and monsoon teleconnections (Randall et al., 2007), though improvement in CMIP5 has been noted for the mean climate, seasonal cycle, intraseasonal and interannual variability (Sperber et al., 2012).

The different monsoon systems are connected through the large-scale tropical circulation, offering the possibility to evaluate a models' representation of monsoon domain and intensity through the global monsoon concept (Wang and Ding, 2008; Wang et al., 2011a). The CMIP5 multi-model ensemble generally reproduces the observed spatial patterns but somewhat underestimates the extent and intensity, especially over Asia and North America (Figure 9.32). The best model has similar performance to the multi-model mean, whereas the poorest models fail to capture the monsoon precipitation domain and intensity over Asia and the western Pacific, Central America, and Australia. Fan et al. (2010) also show that CMIP3 simulations capture the observed trend of weakening of the South Asian summer circulation over the past half century, but are unable to reproduce the magnitude of the observed trend in precipitation. On longer time scales, mid-Holocene simulations show that even though models capture the sign of the monsoon precipitation changes, they tend to underestimate its magnitude (Braconnot et al., 2007b; Zhao and Harrison, 2012)

Poor simulation of the monsoon has been attributed to cold SST biases over the Arabian Sea (Levine and Turner, 2012), a weak meridional temperature gradient (Joseph et al., 2012), unrealistic development of the Indian Ocean dipole (Achuthavarier et al., 2012; Boschat et al.,

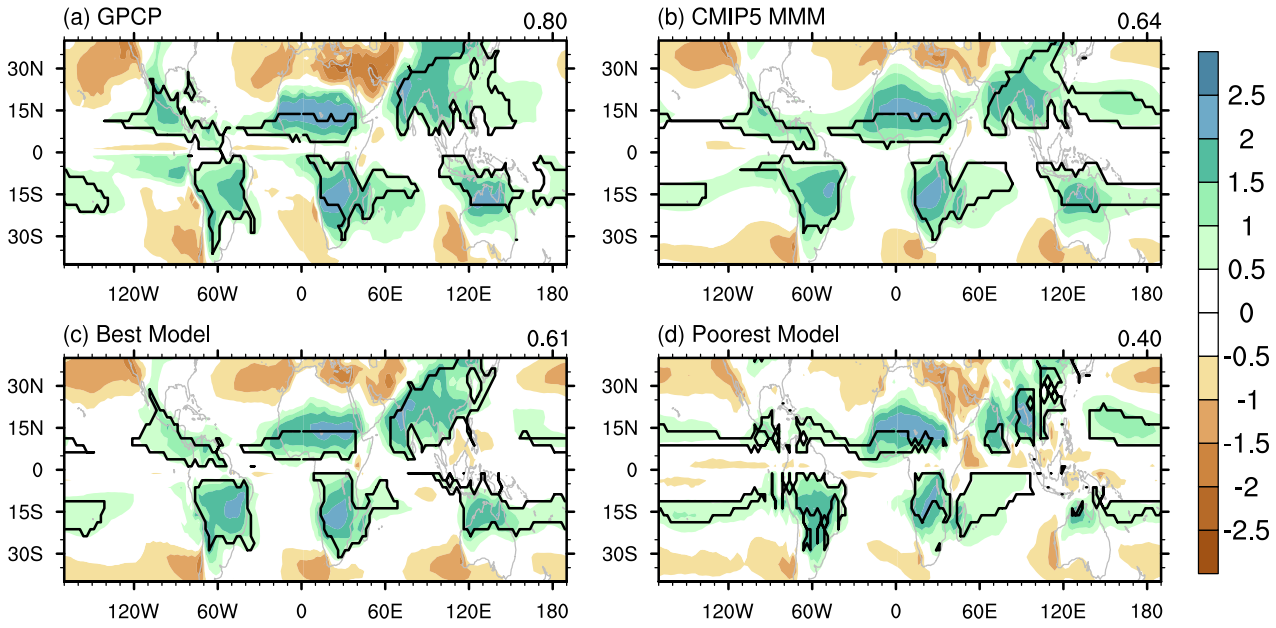

Figure 9.32 | Monsoon precipitation intensity (shading, dimensionless) and monsoon precipitation domain (lines) are shown for (a) observation-based estimates from Global Precipitation Climatology Project (GPCP), (b) the CMIP5 multi-model mean, (c) the best model and (d) the worst model in terms of the threat score for this diagnostic. These measures are based on the seasonal range of precipitation using hemispheric summer (May through September in the Northern Hemisphere (NH)) minus winter (November through March in the NH) values. The monsoon precipitation domain is defined where the annual range is >2.5 mm day^{-1}, and the monsoon precipitation intensity is the seasonal range divided by the annual mean. The threat scores (Wilks, 1995) indicate how well the models represent the monsoon precipitation domain compared to the GPCP data. The threat score in panel (a) is between GPCP and CMAP rainfall to indicate observational uncertainty, whereas in the other panel it is between the simulations and the GPCP observational data set. A threat score of 1.0 would indicate perfect agreement between the two data sets. See Wang and Ding (2008),Wang et al. (2011a), and Kim et al. (2011) for details of the calculations.

2012) and changes to the circulation through excessive precipitation over the southwest equatorial Indian Ocean (Bollasina and Ming, 2013). These biases lead to too weak inland moisture transport and an underestimate of monsoon precipitation over India. Similar SST biases contribute to model-data mismatch in the simulation of the mid-Holocene Asian monsoon (Ohgaito and Abe-Ouchi, 2009), even though the representation of atmospheric processes such as convection seems to dominate the model spread in this region (Ohgaito and Abe-Ouchi, 2009) or over Africa (Zheng and Braconnot, 2013). Factors that have contributed to improved representation of the monsoon in some CMIP5 models include better simulation of topography-related monsoon precipitation due to higher horizontal resolution (Mizuta et al., 2012), a more realistic ENSO–monsoon teleconnection (Meehl et al., 2012) and improved propagation of intraseasonal variations (Sperber and Kim, 2012). The impact of aerosols on monsoon precipitation and its variability is the subject of ongoing investigation (Lau et al., 2008).

These results provide *robust evidence* that CMIP5 models simulate more realistic monsoon climatology and variability than their CMIP3 predecessors, but they still suffer from biases in the representation of the monsoon domain and intensity leading to medium model quality at the global scale and declining quality at the regional scale.

9.5.3 Interannual-to-Centennial Variability

In addition to the annual, intra-seasonal and diurnal cycles described above, a number of other modes of variability arise on multi-annual to multi-decadal time scales (see also Box 2.5). Most of these modes have a particular regional manifestation whose amplitude can be larger than that of human-induced climate change. The observational record is usually too short to fully evaluate the representation of variability in models and this motivates the use of reanalysis or proxies, even though these have their own limitations.

9.5.3.1 Global Surface Temperature Multi-Decadal Variability

The AR4 concluded that modelled global temperature variance at decadal to inter-decadal time scales was consistent with 20th century observations. In addition, results from the last millennium suggest that simulated variability is consistent with indirect estimates (Hegerl et al., 2007).

Figure 9.33a shows simulated internal variability of mean surface temperature from CMIP5 pre-industrial control simulations. Model spread is largest in the tropics and mid to high latitudes (Jones et al., 2012), where variability is also large; however, compared to CMIP3, the spread is smaller in the tropics owing to improved representation of ENSO variability (Jones et al., 2012). The power spectral density of global mean temperature variance in the historical simulations is shown in Figure 9.33b and is generally consistent with the observational estimates.

At longer time scale of the spectra estimated from last millennium simulations, performed with a subset of the CMIP5 models, can be assessed by comparison with different NH temperature proxy records (Figure 9.33c; see Chapter 5 for details). The CMIP5 millennium simulations include natural and anthropogenic forcings (solar, volcanic, GHGs, land use) (Schmidt et al., 2012). Significant differences between unforced and forced simulations are seen for time scale larger than

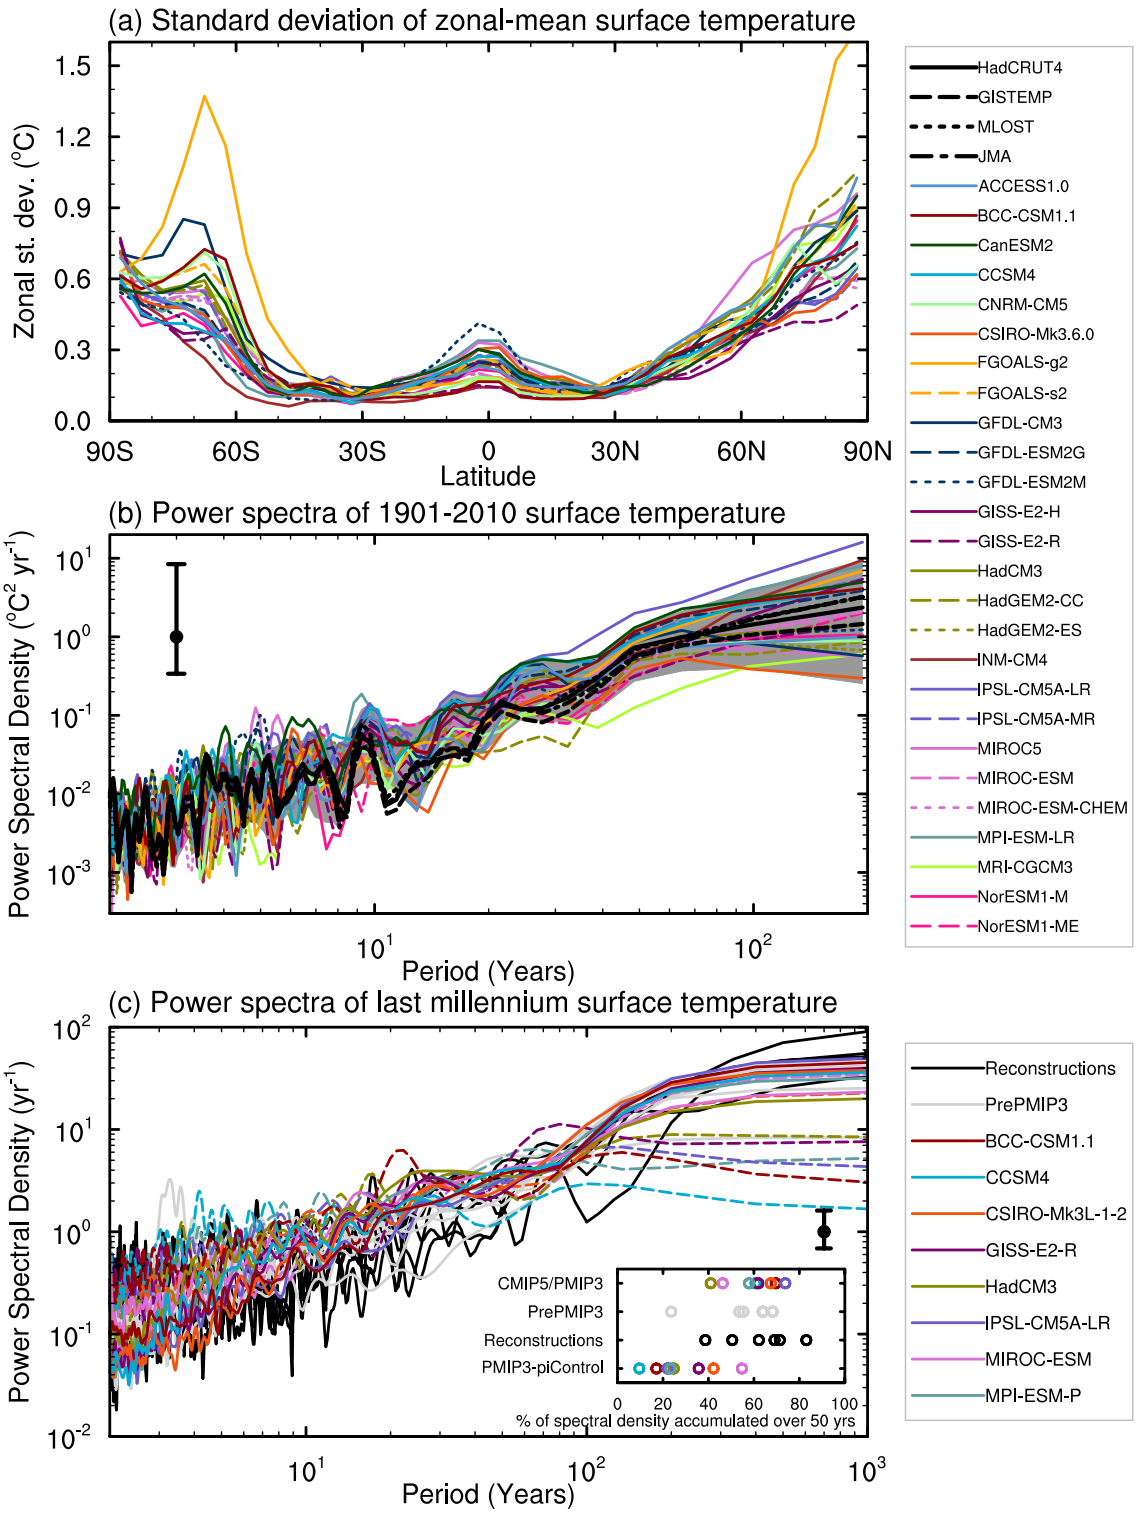

Figure 9.33 | Global climate variability as represented by: (a) Standard deviation of zonal-mean surface temperature of the CMIP5 pre-industrial control simulations (after Jones et al., 2012). (b) Power spectral density for 1901–2010 global mean surface temperature for both historical CMIP5 simulations and the observations (after Jones et al., 2012). The grey shading provides the 5 to 95% range of the simulations. (c) Power spectral density for Northern Hemisphere surface temperature from the CMIP5/ Paleoclimate Modelling Intercomparison Project version 3 (PMIP3) last-millennium simulations (colour, solid) using common external forcing configurations (Schmidt et al., 2012), together with the corresponding pre-industrial simulations (colour, dashed), previous last-millennium AOGCM simulations (black: Fernandez-Donado et al., 2013), and temperature reconstructions from different proxy records (see Section 5.3.5). For comparison between model results and proxy records, the spectra in (c) have been computed from normalized Northern Hemisphere time series. The small panel included in the bottom panel shows for the different models and reconstructions the percentage of spectral density cumulated for periods longer than 50 years, to highlight the differences between unforced (pre-industrial control) and forced (PMIP3 and pre-PMIP3) simulations, compared to temperature reconstruction for the longer time scales. In (b) and (c) the spectra have been computed using a Tukey–Hanning filter of width 97 and 100 years, respectively. The model outputs were not detrended, except for the MIROC-ESM millennium simulation. The 5 to 95% intervals (vertical lines) provide the accuracy of the power spectra estimated given a typical length of 110 years for (b) and 1150 years for (c).

50 years, indicating the importance of forced variability at these time scales (Fernandez-Donado et al., 2013). It should be noted that a few models exhibit slow background climate drift which increases the spread in variance estimates at multi-century time scales. Nevertheless, the lines of evidence above suggest with *high confidence* that models reproduce global and NH temperature variability on a wide range of time scales.

9.5.3.2 Extratropical Circulation, North Atlantic Oscillation and Other Related Dipolar and Annular Modes

Based on CMIP3 models, Gerber et al. (2008) confirmed the AR4 assessment that climate models are able to capture the broad spatial and temporal features of the North Atlantic Oscillation (NAO), but there are substantial differences in the spatial patterns amongst individual models (Casado and Pastor, 2012; Handorf and Dethloff, 2012). Climate models tend to have patterns of variability that are more annular in character than observed (Xin et al., 2008). Models substantially overestimate persistence on sub-seasonal and seasonal time scales, and have difficulty simulating the seasonal cycle of annular mode time scales found in reanalyses (Gerber et al., 2008). The unrealistically long time scale of variability is worse in models with particularly strong equatorward biases in the mean jet location, a result which has been found to hold in the North Atlantic and in the SH (Barnes and Hartmann, 2010; Kidston and Gerber, 2010).

As described in the AR4, climate models have generally been unable to simulate changes as strong as the observed NAO trend over the period 1965–1995, either in coupled mode (Gillett, 2005; Stephenson et al., 2006; Stoner et al., 2009) or forced with observed boundary conditions (Scaife et al. (2009). However, there are a few exceptions to this (e.g., Selten et al., 2004; Semenov et al., 2008), so it is unclear to what extent the underestimation of late 20th century trends reflects model shortcomings versus internal variability. Further evidence has emerged of the coupling of NAO variability between the troposphere and the stratosphere, and even models with improved stratospheric resolution appear to underestimate the vertical coupling (Morgenstern et al., 2010) with consequences for the NAO response to anthropogenic forcing (Sigmond and Scinocca, 2010; Karpechko and Manzini, 2012; Scaife et al., 2012).

The Pacific basin analogue of the NAO, the North Pacific Oscillation (NPO) is a prominent pattern of wintertime atmospheric circulation variability characterized by a north–south dipole in sea level pressure (Linkin and Nigam, 2008). Although climate models simulate the main spatial features of the NPO, many of them are unable to capture the observed linkages with tropical variability and the ocean (Furtado et al., 2011).

Raphael and Holland (2006) showed that coupled models produce a clear Southern Annular Mode (SAM) but that there are relatively large differences between models in terms of the exact shape and orientation of this pattern. Karpechko et al. (2009) found that the CMIP3 models have problems representing linkages between the SAM and SST, surface air temperature, precipitation and particularly sea ice in the Antarctic region.

9.5.3.3 Atlantic Modes

9.5.3.3.1 Atlantic Meridional Overturning Circulation variability

Previous comparisons of the observed and simulated AMOC were restricted to its mean strength, as it had only been sporadically observed (see Chapter 3 and Section 9.4.2.3.1). Continuous AMOC time series now exist for latitudes 41°N (reconstructions since 1993) and 26.5°N (estimate based on direct observations since 2004) (Cunningham et al., 2010; Willis, 2010). At 26.5°N, CMIP3 and CMIP5 model simulations show total AMOC variability that is within the observational uncertainty (Baehr et al., 2009; Marsh et al., 2009; Balan Sarojini et al., 2011; Msadek et al., 2013). However, the total AMOC is the sum of a wind-driven component and a mid-ocean geostrophic component. While both CMIP3 and CMIP5 models tend to overestimate the wind-driven variability, they tend to underestimate the mid-ocean geostrophic variability (Baehr et al., 2009; Balan Sarojini et al., 2011; Msadek et al., 2013). The latter is suggested to result from deficiencies in the simulation of the hydrographic characteristics (Baehr et al., 2009), specifically the Nordic Seas overflows (Yeager and Danabasoglu, 2012; Msadek et al., 2013).

9.5.3.3.2 Atlantic multi-decadal variability/Atlantic Multi-decadal Oscillation

The Atlantic Multi-decadal Variability (AMV), also known as Atlantic Multi-decadal Oscillation (AMO), is a mode of climate variability with an apparent period of about 70 years, and a pattern centred in the North Atlantic Ocean (see Section 14.7.6). In the AR4, it was shown that a number of climate models produced AMO-like multidecadal variability in the North Atlantic linked to variability in the strength of the AMOC. Subsequent analyses has confirmed this, however simulated time scales range from 40 to 60 years (Frankcombe et al., 2010; Park and Latif, 2010; Kavvada et al., 2013), to a century or more (Msadek and Frankignoul, 2009; Menary et al., 2012). In addition, the spatial patterns of variability related to the AMOC differ in many respects from one model to another as shown in Figure 9.34.

The presence of AMO-like variability in unforced simulations, and the fact that forced 20th century simulations in the CMIP3 multi-model ensemble produce AMO variability that is not in phase with that observed, implies the AMO is not predominantly a result of the forcings imposed on the models (Kravtsov and Spannagle, 2008; Knight, 2009; Ting et al., 2009). Results from the CMIP5 models also show a key role for internal variability, alongside a contribution from external forcings in recent decades (Terray, 2012). Historical AMO fluctuations have been better reproduced in a model with a more sophisticated aerosol treatment than was typically used in CMIP3 (Booth et al., 2012a), albeit at the expense of introducing other observational inconsistencies (Zhang et al., 2013). This could suggest that at least part of the AMO may in fact be forced, and that aerosols play a role. In addition to tropospheric aerosols, Otterå et al. (2010) showed the potential for simulated volcanic forcing to have influenced AMO fluctuations over the last 600 years.

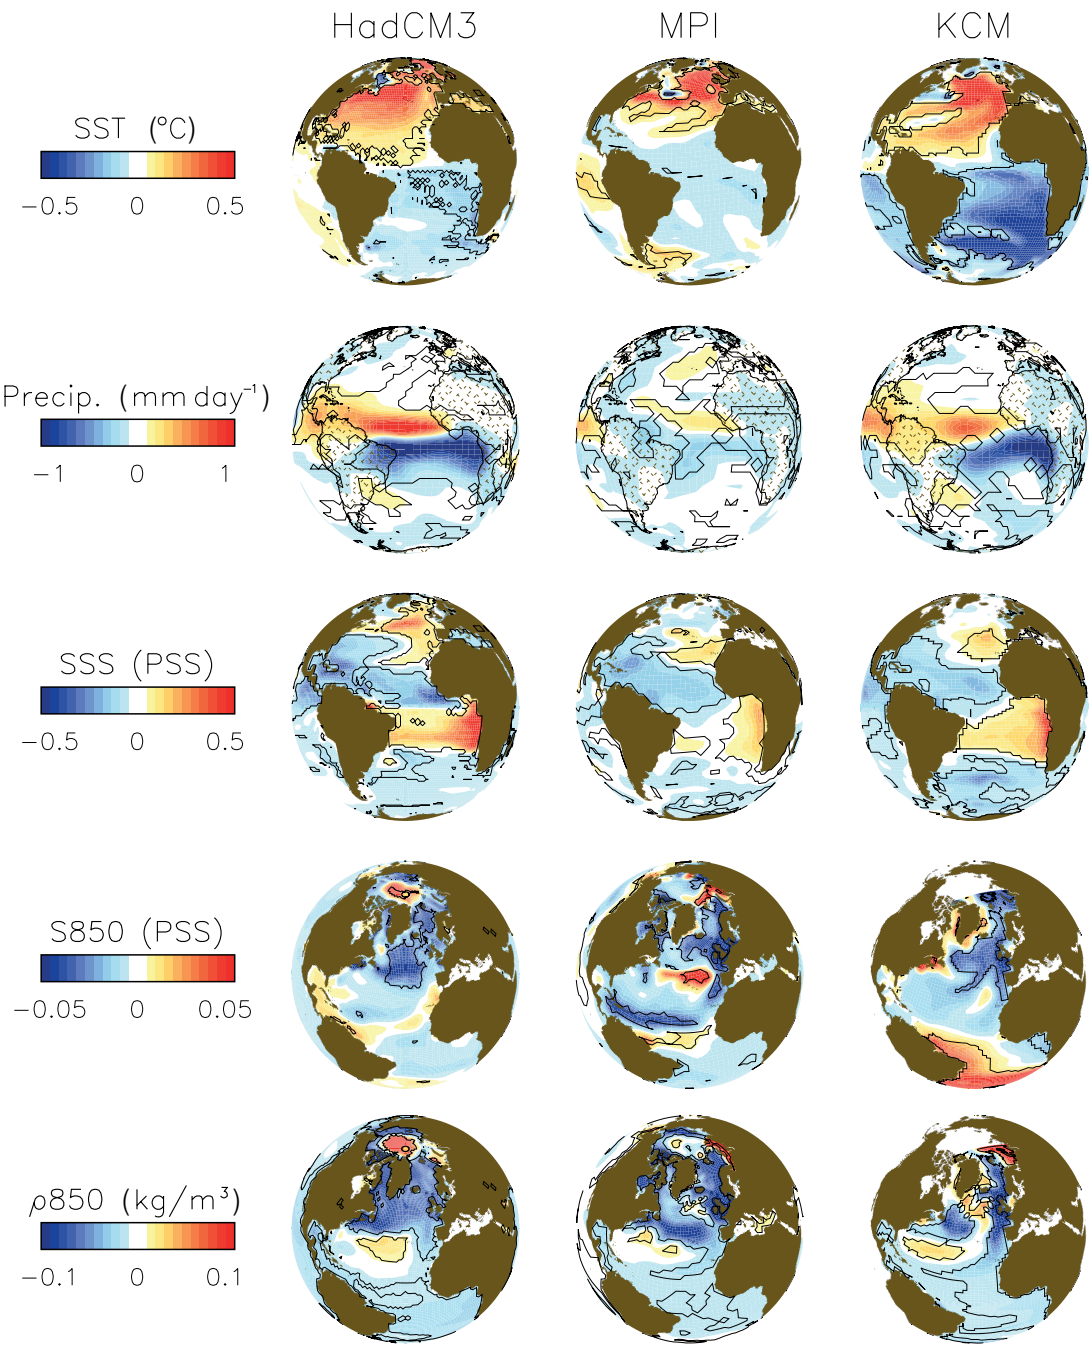

Figure 9.34 | Sequence of physical links postulated to connect Atlantic Meridional Overturning Circulation (AMOC) and Atlantic Multi-decadal Variability (AMV), and how they are represented in three climate models. Shown are regression patters for the following quantities (from top to bottom): sea surface temperature (SST) composites using AMOC time series; precipitation composites using cross-equatorial SST difference time series; equatorial salinity composites using Intertropical Convergence Zone (ITCZ)-strength time series; subpolar-gyre depth-averaged salinity (top 800 to 1000 m) using equatorial salinity time series; subpolar gyre depth averaged density using subpolar gyre depth averaged salinity time series. From left to right: the two CMIP3 models HadCM3 and ECHAM/MPI-OM (MPI), and the non-CMIP model KCM. Black outlining signifies areas statistically significant at the 5% level for a two-tailed t test using the moving-blocks bootstrapping technique (Wilks, 1995). (Figure 3 from Menary et al., 2012.)

9.5.3.3.3 Tropical zonal and meridional modes

The Atlantic Meridional Mode (AMM) is the dominant mode of inter-annual variability in the tropical Atlantic, is characterized by an anomalous meridional shift in the ITCZ (Chiang and Vimont, 2004), and has impacts on hurricane tracks over the North Atlantic (Xie et al., 2005; Smirnov and Vimont, 2011). Virtually all CMIP models simulate AMM-like SST variability in their 20th century climate simulations. However, most models underestimate the SST variance associated with the AMM, and position the north tropical Atlantic SST anomaly too far equatorward. More problematic is the fact that the development of the AMM in many models is led by a zonal mode during boreal winter—a feature that is not observed in nature (Breugem et al., 2006). This spurious AMM behaviour in the models is expected to be associated with the severe model biases in simulating the ITCZ (see Section 9.4.2.5.2).

Atlantic Niño

CMIP3 models have considerable difficulty simulating Atlantic Niño in their 20th century climate simulations. For many models the so-called 'Atl-3' SST index (20°W to 0°W, 3°S to 3°N) displays the wrong seasonality, with the maximum value in either DJF or SON instead of JJA as is observed (Breugem et al., 2006). Despite large biases in the simulated climatology (Section 9.4.2.5.2), about one third of CMIP5 models capture some aspects of Atlantic Niño variability, including amplitude, spatial pattern and seasonality (Richter et al., 2013). This represents an improvement over CMIP3.

9.5.3.4 Indo-Pacific Modes

9.5.3.4.1 El Niño-Southern Oscillation

The ENSO phenomenon is the dominant mode of climate variability on seasonal to interannual time scales (see Wang and Picaut (2004) and Chapter 14). The representation of ENSO in climate models has steadily improved and now bears considerable similarity to observed ENSO properties (AchutaRao and Sperber, 2002; Randall et al., 2007; Guilyardi et al., 2009b). However, as was the case in the AR4, simulations

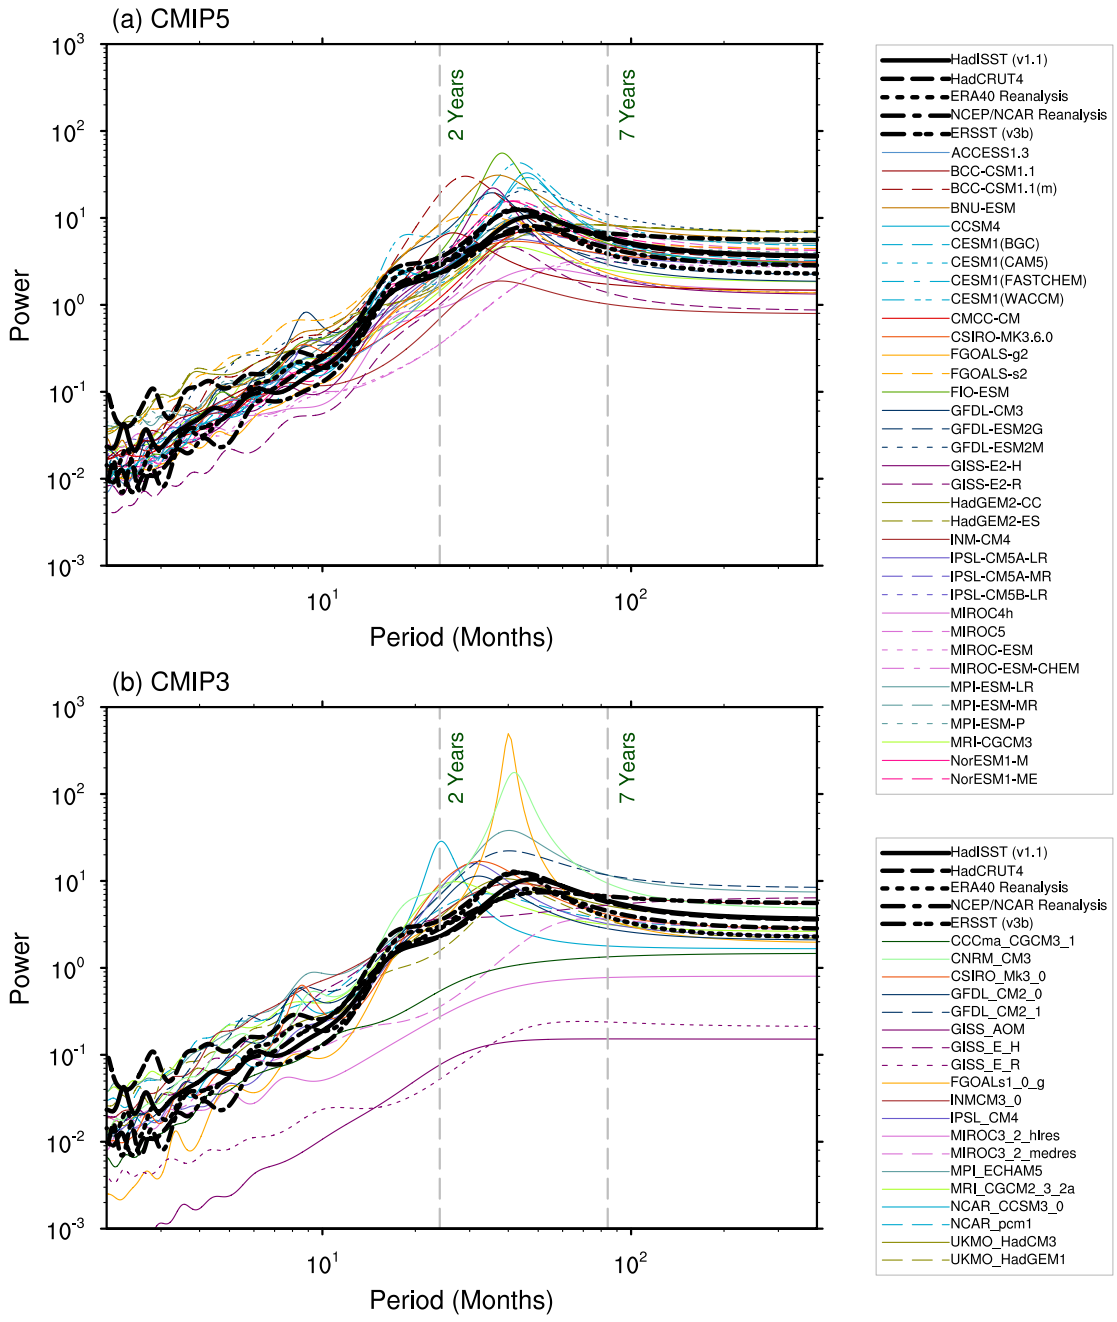

Figure 9.35 | Maximum entropy power spectra of surface air temperature averaged over the NINO3 region (5°N to 5°S, 150°W to 90°W) for (a) the CMIP5 models and (b) the CMIP3 models. ECMWF reanalysis in (a) refers to the European Centre for Medium Range Weather Forecasts (ECMWF) 15-year reanalysis (ERA15). The vertical lines correspond to periods of two and seven years. The power spectra from the reanalyses and for SST from the Hadley Centre Sea Ice and Sea Surface Temperature (HadISST) version 1.1, Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRU 4), ECMWF 40-year reanalysis (ERA40) and National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR) data set are given by the series of black curves. (Adapted from AchutaRao and Sperber, 2006.)

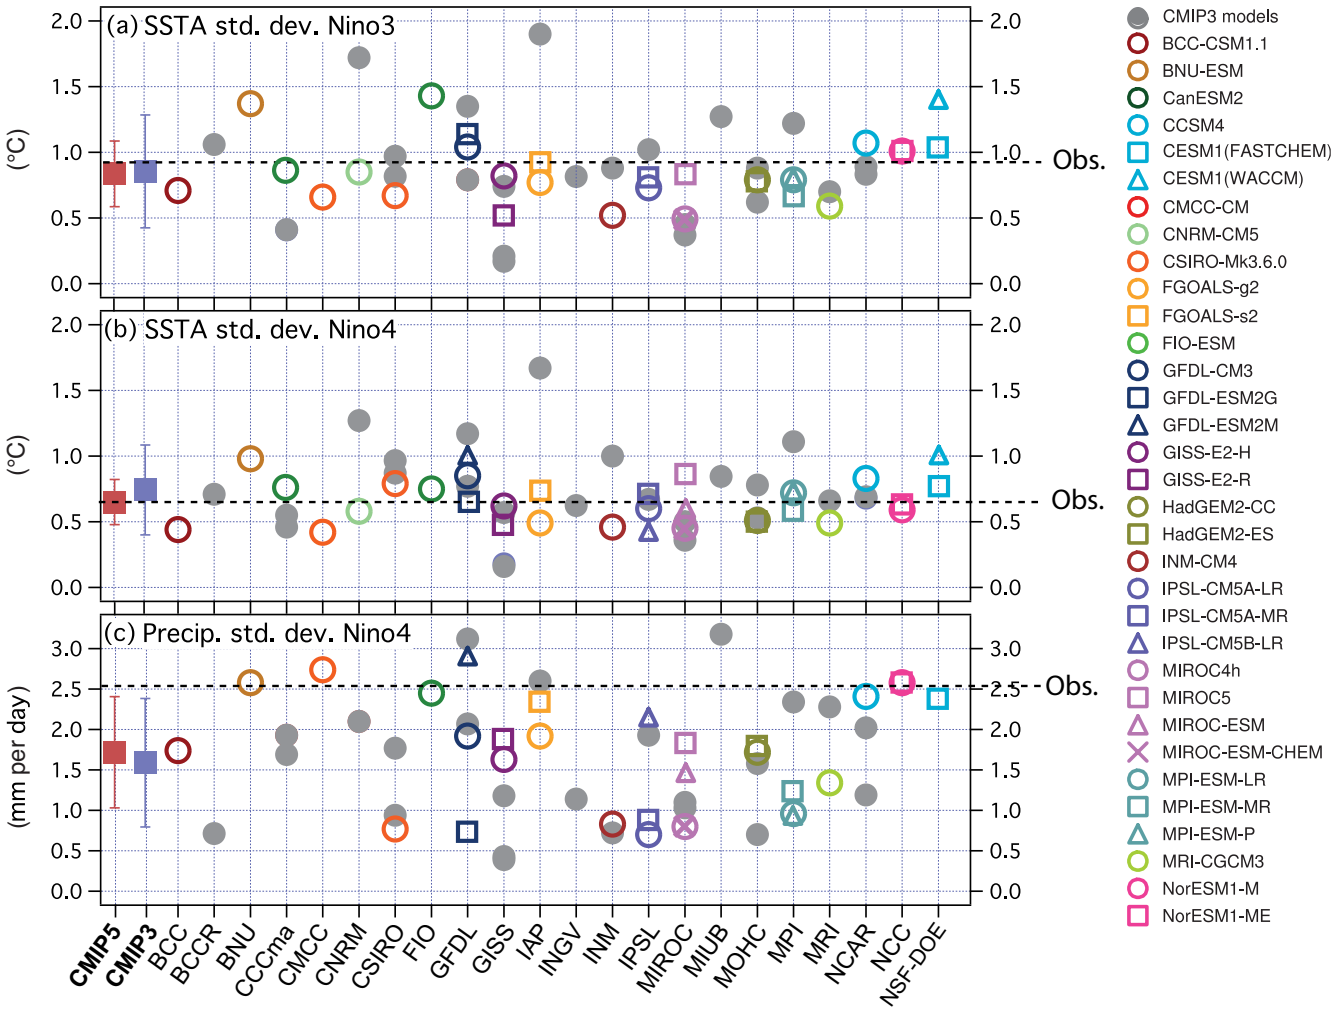

Figure 9.36 | ENSO metrics for pre-industrial control simulations in CMIP3 and CMIP5. (a) and (b): SST anomaly standard deviation (°C) in Niño 3 and Niño 4, respectively, (c) precipitation response (standard deviation, mm/day) in Niño4. Reference data sets, shown as dashed lines: Hadley Centre Sea Ice and Sea Surface Temperature (HadISST) version 1.1 for (a) and (b), CPC Merged Analysis of Precipitation (CMAP) for (c). The CMIP5 and CMIP3 multi-model means are shown as squares on the left of each panel with the whiskers representing the model standard deviation. Individual CMIP3 models shown as filled grey circles, and individual CMIP5 models are identified in the legend.

of both background climate (time mean and seasonal cycle, see Section 9.4.2.5.1) and internal variability exhibit serious systematic errors (van Oldenborgh et al., 2005; Capotondi et al., 2006; Guilyardi, 2006; Wittenberg et al., 2006; Watanabe et al., 2011; Stevenson et al., 2012; Yeh et al., 2012), many of which can be traced to the representation of deep convection, trade wind strength and cloud feedbacks, with little improvement from CMIP3 to CMIP5 (Braconnot et al., 2007a; L'Ecuyer and Stephens, 2007; Guilyardi et al., 2009a; Lloyd et al., 2009, 2010; Sun et al., 2009; Zhang and Jin, 2012).

While a number of CMIP3 models do not exhibit an ENSO variability maximum at the observed 2- to 7- year time scale, most CMIP5 models do have a maximum near the observed range and fewer models have the tendency for biennial oscillations (Figure 9.35; see also Stevenson, 2012). In CMIP3 the amplitude of El Niño ranged from less than half to more than double the observed amplitude (van Oldenborgh et al., 2005; AchutaRao and Sperber, 2006; Guilyardi, 2006; Guilyardi et al., 2009b). By contrast, the CMIP5 models show less inter-model spread (Figure 9.36; Kim and Yu, 2012). The CMIP5 models still exhibit errors in ENSO amplitude, period, irregularity, skewness, spatial patterns (Lin, 2007; Leloup et al., 2008; Guilyardi et al., 2009b; Ohba et al., 2010; Yu and Kim, 2011; Su and Jiang, 2012) or teleconnections (Watanabe et al., 2012; Weller and Cai, 2013a).

Since AR4, new analysis methods have emerged and are now being applied. For example, Jin et al. (2006) and Kim and Jin (2011a) identified five different feedbacks affecting the Bjerknes (or BJ) index, which in turn characterizes ENSO stability. Kim and Jin (2011b) applied this process-based analysis to the CMIP3 multi-model ensemble and demonstrated a significant positive correlation between ENSO amplitude and the BJ index. When respective components of the BJ index obtained from the coupled models were compared with those from observations, it was shown that most coupled models underestimated the negative thermal damping feedback (Lloyd et al., 2012; Chen et al., 2013) and the positive zonal advective and thermocline feedbacks.

Detailed quantitative evaluation of ENSO performance is hampered by the short observational record of key processes (Wittenberg, 2009; Li et al., 2011b; Deser et al., 2012) and the complexity and diversity of the processes involved (Wang and Picaut, 2004). While shortcomings

remain (Guilyardi et al., 2009b), the CMIP5 model ensemble shows some improvement compared to CMIP3, but there has been no major breakthrough and the multi-model improvement is mostly due to a reduced number of poor-performing models.

9.5.3.4.2 Indian Ocean basin and dipole modes

Indian Ocean SST displays a basin-wide warming following El Niño (Klein et al., 1999). This Indian Ocean basin (IOB) mode peaks in boreal spring and persists through the following summer. Most CMIP5 models capture this IOB mode, an improvement over CMIP3 (Du et al., 2013). However, only about half the CMIP5 models capture its long temporal persistence, and these models tend to simulate ENSO-forced ocean Rossby waves in the tropical south Indian Ocean (Zheng et al., 2011).

The Indian Ocean zonal dipole mode (IOD) (Saji et al., 1999; Webster et al., 1999) appears to be part of a hemispheric response to tropical atmospheric forcing (Fauchereau et al., 2003; Hermes and Reason, 2005). Most CMIP3 models are able to reproduce the general features of the IOD, including its phase lock onto the July to November season (Saji et al., 2006). The modelled SST anomalies, however, tend to show too strong a westward extension along the equator in the eastern Indian Ocean. CMIP3 models exhibit considerable spread in IOD amplitude, some of which can be explained by differences in the strength of the simulated Bjerknes feedback (Liu et al., 2011; Cai and Cowan, 2013). No substantial change is seen in CMIP5 (Weller and Cai, 2013a).

Many models simulate the observed correlation between IOD and ENSO. The magnitude of this correlation varies substantially between models, but is apparently not tied to the amplitude of ENSO (Saji et al., 2006). A subset of CMIP3 models show a spurious correlation with ENSO following the decay of ENSO events, instead of during the ENSO developing phase, possibly due to erroneous representation of oceanic pathways connecting the equatorial Pacific and Indian Oceans (Cai et al., 2011).

9.5.3.4.3 Tropospheric biennial oscillation

The tropospheric biennial oscillation (TBO, Section 14.7.4) is a biennial tendency of many phenomena in the Indo-Pacific region that affects droughts and floods over large areas of south Asia and Australia (e.g., Chang and Li, 2000; Li et al., 2001; Meehl et al., 2003). The IOD involves regional patterns of SST anomalies in the TBO in the Indian Ocean during the northern fall season following the south Asian monsoon (Loschnigg et al., 2003). The TBO has been simulated in a number of global coupled climate model simulations (e.g., Ogasawara et al., 1999; Loschnigg et al., 2003; Nanjundiah et al., 2005; Turner et al., 2007; Meehl and Arblaster, 2011).

9.5.3.5 Indo-Pacific Teleconnections

Tropical SST variability provides a significant forcing of atmospheric teleconnections and drives a large portion of the climate variability over land (Goddard and Mason, 2002; Shin et al., 2010). Although local forcings and feedbacks can play an important role (Pitman et al., 2012a), the simulation of land surface temperatures and precipitation requires accurate predictions of SST patterns (Compo and Sardeshmukh, 2009; Shin et al., 2010) as well as zonal wind variability patterns (Handorf and Dethloff, 2012). Teleconnections hence play a central role in regional climate change (see Chapter 14).

9.5.3.5.1 Teleconnections affecting North America

The Pacific North American (PNA) pattern is a wavetrain-like pattern in mid-level geopotential heights. The majority of CMIP3 models simulate the spatial structure of the PNA pattern in wintertime (Stoner et al., 2009). The PNA pattern has contributions from both internal atmospheric variability (Johnson and Feldstein, 2010) and ENSO and PDO teleconnections (Deser et al., 2004). The power spectrum of this temporal behaviour is generally captured by the CMIP3 models, although the level of year-to-year autocorrelation varies according to the strength of the simulated ENSO and PDO (Stoner et al., 2009).

9.5.3.5.2 Tropical ENSO teleconnections

These moist teleconnection pathways involve mechanisms related to those at play in the precipitation response to global warming (Chiang and Sobel, 2002; Neelin et al., 2003) and provide challenging test statistics for model precipitation response. Compared to earlier generation climate models, CMIP3 and CMIP5 models tend to do somewhat better (Neelin, 2007; Cai et al., 2009; Coelho and Goddard, 2009; Langenbrunner and Neelin, 2013) at precipitation reductions associated with El Niño over equatorial South America and the Western Pacific, although CMIP5 offers little further improvement over CMIP3 (see for instance the standard deviation of precipitation in the western Pacific in Figure 9.36). CMIP5 models simulate the sign of the precipitation change over broad regions, and do well at predicting the amplitude of the change (for a given SST forcing) (Langenbrunner and Neelin, 2013).

A regression of the West African monsoon precipitation index with global SSTs reveals two major teleconnections (Fontaine and Janicot, 1996). The first highlights the strong influence of ENSO, while the second reveals a relationship between the SST in the Gulf of Guinea and the northward migration of the monsoon rain belt over West Africa. Most CMIP3 models show a single dominant Pacific teleconnection, which is, however, of the wrong sign for half of the models (Joly et al., 2007). Only one model shows a significant second mode, emphasizing the difficulty in simulating the response of the African rain belt to Atlantic SST anomalies that are not synchronous with Pacific anomalies.

Both CMIP3 and CMIP5 models have been evaluated and found to vary in their abilities to represent both the seasonal cycle of correlations between the Niño 3.4 and North Australian SSTs (Catto et al., 2012a, 2012b) with little change in quality from CMIP3 to CMIP5. Generally the models do not capture the strength of the negative correlations during the second half of the year. The models also still struggle to capture the SST evolution in the North Australian region during El Niño and La Niña. Teleconnection patterns from both ENSO and the Indian Ocean Dipole to precipitation over Australia are reasonably well simulated in the key September-November season (Cai et al., 2009; Weller and Cai, 2013b) in the CMIP3 and CMIP5 multi-model mean.

9.5.3.6 Pacific Decadal Oscillation and Interdecadal Pacific Oscillation

The Pacific Decadal Oscillation (PDO) refers to a mode of variability involving SST anomalies over the North Pacific (north of 20°N) (Mantua et al., 1997). Although the PDO time series exhibits considerable decadal variability, it is difficult to ascertain whether there are any robust spectral peaks given the relatively short observational record (Minobe, 1997, 1999; Pierce, 2001; Deser et al., 2004). The ability of climate models to represent the PDO has been assessed by Stoner et al. (2009) and Furtado et al. (2011). Their results indicate that approximately half of the CMIP3 models simulate the observed spatial pattern and temporal behaviour (e.g., enhanced variance at low frequencies); however, spectral peaks are consistently higher in frequency than those suggested by the short observational record. The modelled PDO correlation with SST anomalies in the tropical Indo-Pacific are strongly underestimated by the CMIP3 models (Wang et al., 2010; Deser et al., 2011; Furtado et al., 2011; Lienert et al., 2011). Climate models have been shown to simulate features of the closely related Interdecadal Pacific Oscillation (IPO, based on SSTs over the entire Pacific basin; see Section 14.7.3; Power and Colman, 2006; Power et al., 2006; Meehl et al., 2009), although deficiencies remain in the strength of the tropical–extratropical connections.

9.5.3.7 The Quasi-Biennial Oscillation

Significant progress has been made in recent years to model and understand the impacts of the Quasi-Biennial Oscillation (QBO; Baldwin et al., 2001). Many climate models have now increased their vertical domain and/or improved their physical parameterizations (see Tables 9.1 and 9.A.1), and some of these reproduce a QBO (e.g., HadGEM2, MPI-ESM-LR, MIROC). Many features of the QBO such as its width and phase asymmetry also appear spontaneously in these simulations due to internal dynamics (Dunkerton, 1991; Scaife et al., 2002; Haynes, 2006). Some of the QBO effects on the extratropical climate (Holton and Tan, 1980; Hamilton, 1998; Naoe and Shibata, 2010) as well as ozone (Butchart et al., 2003; Shibata and Deushi, 2005) are also reproduced in models.

9.5.3.8 Summary

In summary, most modes of interannual to interdecadal variability are now present in climate models. As in AR4, their assessment presents a varied picture and CMIP5 models only show a modest improvement over CMIP3, mostly due to fewer poor-performing models. New since the AR4, process-based model evaluation is now helping identify sources of specific biases, although the observational record is often too short or inaccurate to offer strong constraints. The assessment of modes and patterns is summarized in Table 9.4.

9.5.4 Extreme Events

Extreme events are realizations of the tail of the probability distribution of weather and climate variability. They are higher-order statistics and thus generally more difficult to realistically represent in climate models. Shorter time scale extreme events are often associated with smaller scale spatial structure, which may be better represented as model resolution increases. In the AR4, it was concluded that models could simulate the statistics of extreme events better than expected from the generally coarse resolution of the models at that time, especially for temperature extremes (Randall et al., 2007).

Table 9.4 | Summary of assessment of interannual to interdecadal variability in climate models. See also Figure 9.44.

	Short Name	Level of Confidence	Level of Evidence for Evaluation	Degree of Agreement	Model Quality	Difference with AR4 (including CMIP5 vs. CMIP3)	Section
Global sea surface temperature (SST) variability	SST-var	*High*	*Robust*	*Medium*	Medium	Slight improvement in the tropics	9.5.3.1

The IPCC has conducted an assessment of extreme events in the context of climate change—the Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX) (IPCC, 2012). Although there is no comprehensive climate model evaluation with respect to extreme events in SREX, there is some consideration of model performance taken into account in assessing uncertainties in projections.

9.5.4.1 Extreme Temperature

Since the AR4, evaluation of CMIP3 and CMIP5 models has been undertaken with respect to temperature extremes. Both model ensembles simulate present-day warm extremes, in terms of 20-year return values, reasonably well, with errors typically within a few degrees Celsius over most of the globe (Kharin et al., 2007; Kharin et al., 2012). The CMIP5 and CMIP3 models perform comparably for various temperature extreme indices, but with smaller inter-model spread in CMIP5.The inter-model range of simulated indices is similar to the spread amongst observationally based estimates in most regions (Sillmann et al., 2013). Figure 9.37 shows relative error estimates of available CMIP5 models for various extreme indices based on Sillmann et al. (2013). Although the relative performance of an individual model may depend on the choice of the reference data set (four different reanalyses are used), the mean and median models tend to outperform individual models. According to the standardized multi-model median errors ($RMSE_{std}$) for CMIP3 and CMIP5 shown on the right side of Figure 9.37, the performance of the two ensembles is similar.

In terms of historical trends, CMIP3 and CMIP5 models generally capture observed trends in temperature extremes in the second half of the 20th century (Sillmann et al., 2013), as illustrated in Figure 9.37. The modelled trends are consistent with both reanalyses and station-based estimates. It is also clear in the figure that model-based indices respond coherently to major volcanic eruptions. Detection and attribution studies based on CMIP3 models suggest that models tend to overestimate the observed warming of warm temperature extremes and underestimate the warming of cold extremes in the second half of 20th century (Christidis et al., 2011; Zwiers et al., 2011) as noted in SREX (Seneviratne et al., 2012). See also Chapter 10. This is not as obvious in the CMIP5 model evaluation (Figure 9.37 and Sillmann et al. (2013)) and needs further investigation.

9.5.4.2 Extreme Precipitation

For extreme precipitation, observational uncertainty is much larger than for temperature, making model evaluation more challenging. Discrepancies between different reanalyses for extreme precipitation are substantial, whereas station-based observations have limited spatial coverage (Kharin et al., 2007, 2012; Sillmann et al., 2013). Moreover, a station-based observational data set, which is interpolated from station measurements, has a potential mismatch of spatial scale when compared to model results or reanalyses (Chen and Knutson, 2008). Uncertainties are especially large in the tropics. In the extratropics, precipitation extremes in terms of 20-year return values simulated by CMIP3 and CMIP5 models compared relatively well with the observational data sets, with typical discrepancies in the 20% range (Kharin et al., 2007, 2012). Figure 9.37 shows relative errors of CMIP5 models for five precipitation-related indices. Darker grey shadings in the RMSE columns for precipitation indicate larger discrepancies between models and reanalyses for precipitation extremes in general. Sillmann et al. (2013) found that the CMIP5 models tend to simulate more intense precipitation and fewer consecutive wet days than the CMIP3, and thus are closer to the observationally based indices.

It is known from sensitivity studies that simulated extreme precipitation is strongly dependent on model resolution. Growing evidence has shown that high-resolution models (50 km or finer in the atmosphere) can reproduce the observed intensity of extreme precipitation (Wehner et al., 2010; Endo et al., 2012; Sakamoto et al., 2012), though some of these results are based on models with observationally constrained surface or lateral boundary conditions (i.e., Atmospheric General Circulation Models (AGCMs) or Regional Climate Models (RCMs)).

In terms of historical trends, a detection and attribution study by Min et al. (2011) found consistency in sign between the observed increase in heavy precipitation over NH land areas in the second half of the 20th century and that simulated by CMIP3 models, but they found that the models tend to underestimate the magnitude of the trend (see also Chapter 10). Related to this, it has been pointed out from comparisons to satellite-based data sets that the majority of models underestimate the sensitivity of extreme precipitation intensity to temperature in the tropics (Allan and Soden, 2008; Allan et al., 2010; O'Gorman, 2012) and globally (Liu et al., 2009; Shiu et al., 2012). O'Gorman (2012) showed that this implies possible underestimation of the projected future increase in extreme precipitation in the tropics.

9.5.4.3 Tropical Cyclones

It was concluded in the AR4 that high-resolution AGCMs generally reproduced the frequency and distribution, but underestimated intensity of tropical cyclones (Randall et al., 2007). Since then, Mizuta et al. (2012) have shown that a newer version of the MRI-AGCM with improved parameterizations (at 20 km horizontal resolution) simulates tropical cyclones as intense as those observed with improved distribution as well. Another remarkable finding since the AR4 is that the observed year-to-year count variability of Atlantic hurricanes can be well simulated by modestly high resolution (100 km or finer) AGCMs forced by observed SST, though with less skill in other basins (Larow et al., 2008; Zhao et al., 2009; Strachan et al., 2013). Vortices that have some characteristics of tropical cyclones can also be detected and tracked in AOGCMs in CMIP3 and 5, but their intensities are generally too weak (Yokoi et al., 2009a; Yokoi et al., 2012; Tory et al., 2013; Walsh et al., 2013).

9.5.4.4 Droughts

Drought is caused by long time scale (months or longer) variability of both precipitation and evaporation. Sheffield and Wood (2008) found that models in the CMIP3 ensemble simulated large-scale droughts in the 20th century reasonably well, in the sense that multi-model spread includes the observational estimate in each of several regions. However, it should be noted that there are various definitions of drought (see Chapter 2 and Seneviratne et al., 2012) and the performance of simulated drought can depend on the definition. Moreover, different models

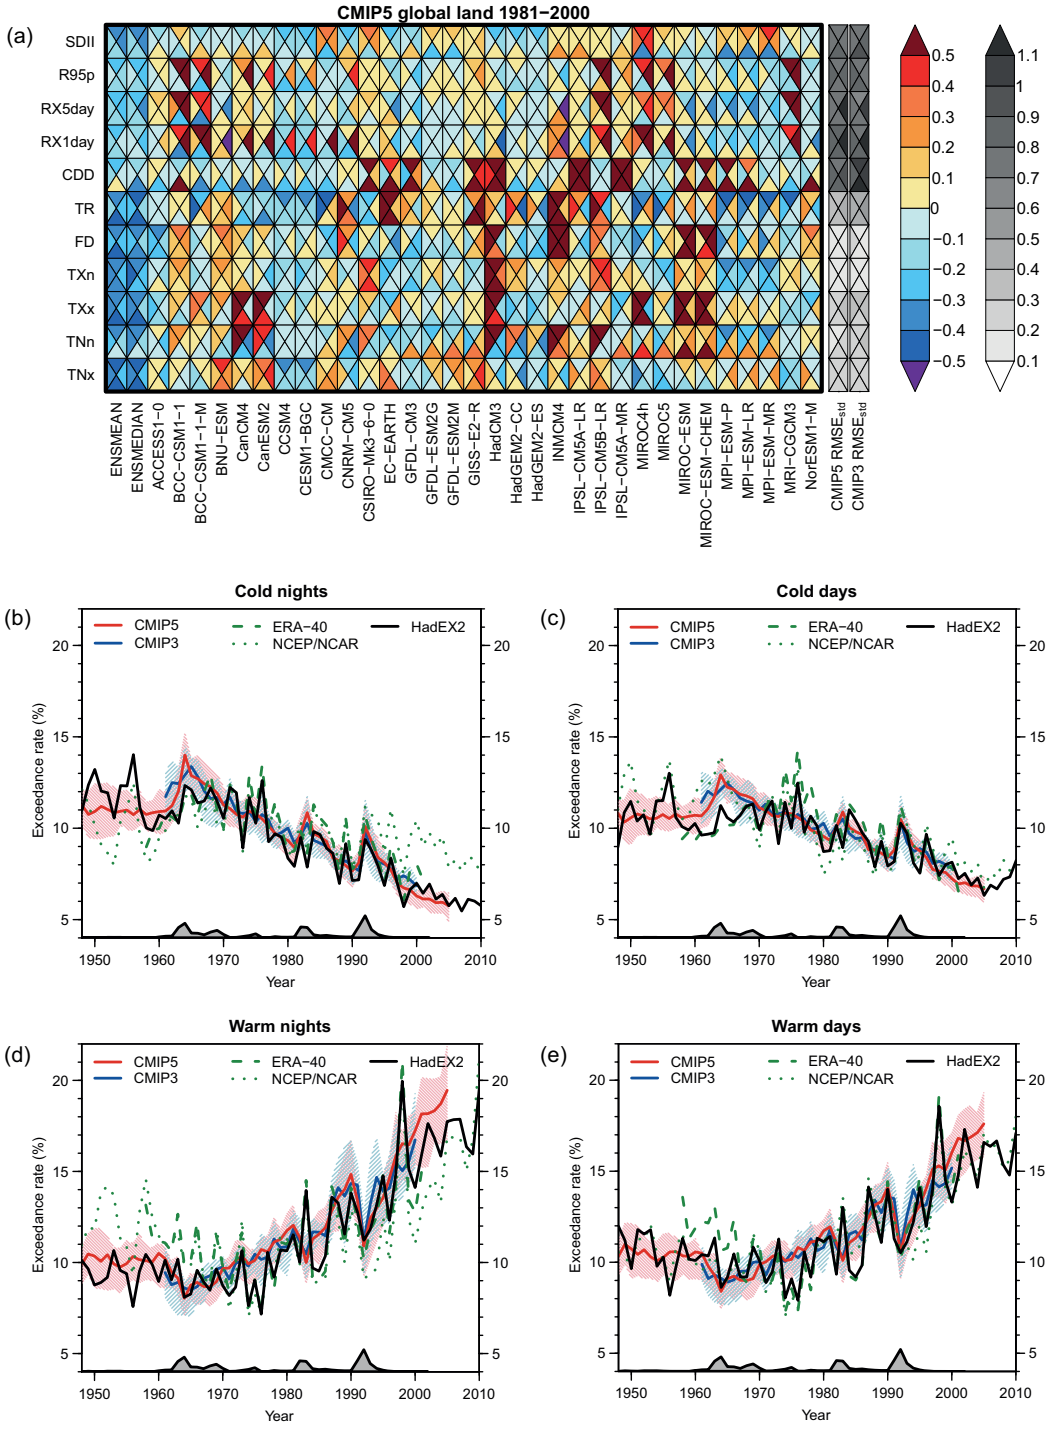

Figure 9.37 | (a) Portrait plot of relative error metrics for the CMIP5 temperature and precipitation extreme indices based on Sillmann et al. (2013). (b)–(e) Time series of global mean temperature extreme indices over land from 1948 to 2010 for CMIP3 (blue) and CMIP5 (red) models, ECMWF 40-year reanalysis (ERA40, green dashed) and National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR, green dotted) reanalyses and HadEX2 station-based observational data set (black) based on Sillmann et al. (2013). In (a), reddish and bluish colours indicate, respectively, larger and smaller root-mean-square (RMS) errors for an individual model relative to the median model. The relative error is calculated for each observational data set separately. The grey-shaded columns on the right side indicate the RMS error for the multi-model median standardized by the spatial standard deviation of the index climatology in the reanalysis, representing absolute errors for CMIP3 and CMIP5 ensembles. Results for four different reference data sets, ERA-interim (top), ERA40 (left), NCEP/NCAR (right) and NCEP- Department of Energy (DOE) (bottom) reanalyses, are shown in each box. The analysis period is 1981–2000, and only land areas are considered. The indices shown are simple daily precipitation intensity index (SDII), very wet days (R95p), annual maximum 5-day/1-day precipitation (RX5day/RX1day), consecutive dry days (CDD), tropical nights (TR), frost days (FD), annual minimum/maximum daily maximum surface air temperature (TXn/TXx), and annual minimum/maximum daily minimum surface air temperature (TNn/TNx). See Box 2.4 for the definitions of indices. Note that only a small selection of the indices analysed in Sillmann et al. (2013) is shown, preferentially those that appear in Chapters 2, 10, 11, 12, 14. Also note that the NCEP/NCAR reanalysis has a known defect for TXx (Sillmann et al., 2013), but its impact on this figure is small. In (b)–(e), shading for model results indicates the 25th to 75th quantile range of inter-model spread. Grey shading along the horizontal axis indicates the evolution of globally averaged volcanic forcing according to Sato et al. (1993). The indices shown are the frequency of daily minimum/maximum surface air temperature below the 10th percentile (b: Cold nights/c: Cold days) and that above 90th percentile (d: Warm nights/e: Warm days) of the 1961–1990 base period. Note that, as these indices essentially represent changes relative to the base period, they are particularly suitable for being shown in time series and not straightforward for being shown in (a).

can simulate drought with different mechanisms (McCrary and Randall, 2010; Taylor et al., 2012a). A comprehensive evaluation of CMIP5 models for drought is currently not available, although Sillmann et al. (2013) found that consecutive dry days simulated by CMIP5 models are comparable to observations in magnitude and distribution.

9.5.4.5 Summary

There is *medium evidence* (i.e., a few multi-model studies) and *high agreement* that the global distribution of temperature extremes are represented well by CMIP3 and CMIP5 models. The observed global warming trend of temperature extremes in the second half of the 20th century is reproduced in models, but there is *medium evidence* (a few CMIP3 studies) and *medium agreement* (not evident in a preliminary look at CMIP5) that models tend to overestimate the warming of warm temperature extremes and underestimate the warming of cold temperature extremes.

There is *medium evidence* (single multi-model study) and *medium agreement* (as inter-model difference is large) that CMIP5 models tend to simulate more intense and thus more realistic precipitation extremes than CMIP3, which could be partly due to generally higher horizontal resolution. There is *medium evidence* and *high agreement* that CMIP3 models tend to underestimate the sensitivity of extreme precipitation intensity to temperature. There is *medium evidence* and *high agreement* that high resolution (50 km or finer) AGCMs tend to simulate the intensity of extreme precipitation comparable to observational estimates.

There is *medium evidence* and *high agreement* that year-to-year count variability of Atlantic hurricanes can be well simulated by modestly high resolution (100 km or finer) AGCMs forced by observed SSTs. There is *medium evidence* and *medium agreement* (as inter-model difference is large) that the intensity of tropical cyclones is too weak in CMIP3 and CMIP5 models. Finally, there is *medium evidence* (a few multi-model studies) and *medium agreement* (as it might depend on definitions of drought) that models can simulate aspects of large-scale drought.

Box 9.3 | Understanding Model Performance

This Box provides a synthesis of findings on understanding model performance based on the model evaluations discussed in this chapter.

Uncertainty in Process Representation

Some model errors can be traced to uncertainty in representation of processes (parameterizations). Some of these are long-standing issues in climate modelling, reflecting our limited, though gradually increasing, understanding of very complex processes and the inherent challenges in mathematically representing them. For the atmosphere, cloud processes, including convection and its interaction with boundary layer and larger-scale circulation, remain major sources of uncertainty (Section 9.4.1). These in turn cause errors or uncertainties in radiation which propagate through the coupled climate system. Distribution of aerosols is also a source of uncertainty arising from modelled microphysical processes and transport (Sections 9.4.1 and 9.4.6). Ocean models are subject to uncertainty in parameterizations of vertical and horizontal mixing and convection (Sections 9.4.2, 9.5.2 and 9.5.3), and ocean errors in turn affect the atmosphere through resulting SST biases. Simulation of sea ice is also affected by errors in both the atmosphere and the ocean as well as the parameterization of sea ice itself (Section 9.4.3). With respect to biogeochemical components in Earth System Models (ESMs), parameterizations of nitrogen limitation and forest fires are thought to be important for simulating the carbon cycle, but very few ESMs incorporate these so far (Sections 9.4.4 and 9.4.5).

Error Propagation

Causes of one model bias can sometimes be associated with another. Although the root cause of those biases is often unclear, knowledge of the causal chain or a set of interrelated biases can provide a key to further understanding and improvement of model performance. For example, biases in storm track position are partly due to a SST biases in the Gulf Stream and Kuroshio Current (Section 9.4.1). Some biases in variability or trend can be partly traced back to biases in mean states. The decreasing trend in September Arctic ice extent tends to be underestimated when sea ice thickness is overestimated (Section 9.4.3). In such cases, improvement of the mean state may improve simulated variability or trend.

Sensitivity to Resolution

Some phenomena or aspects of climate are found to be better simulated with models run at higher horizontal and/or vertical resolution. In particular, increased resolution in the atmosphere has improved, at least in some models, storm track and extratropical cyclones (Section 9.4.1), diurnal variation of precipitation over land (Section 9.5.2), extreme precipitation, and tropical cyclone intensity and structure (Section 9.5.4). Similarly, increased horizontal resolution in the ocean is shown to improve sea surface height variability, western boundary currents, tropical instability waves and coastal upwelling (Section 9.4.2), and variability of Atlantic meridional overturning circulation (Section 9.5.3). High vertical resolution and a high model top, as well as high horizontal resolution, are important for simulating lower stratospheric climate variability (Section 9.4.1), blocking (Section 9.5.2), the Quasi-Biennial Oscillation and the North Atlantic Oscillation (Section 9.5.3). *(continued on next page)*

Box 9.3 (continued)

Uncertainty in Observational Data

In some cases, insufficient length or quality of observational data makes model evaluation challenging, and is a frequent problem in the evaluation of simulated variability or trends. This is evident for evaluation of upper tropical tropospheric temperature, tropical atmospheric circulation (Section 9.4.1), the Atlantic meridional overturning circulation, the North Atlantic Oscillation and the Pacific Decadal Oscillation (Section 9.5.3). Data quality has been pointed out as an issue for arctic cloud properties (Section 9.4.1), ocean heat content, heat and fresh water fluxes over the ocean (Section 9.4.2) and extreme precipitation (Section 9.5.4). Palaeoclimate reconstructions also have large inherent uncertainties (Section 9.5.2). It is clear therefore that updated or newly available data affect model evaluation conclusions.

Other Factors

Model evaluation can be affected by how models are forced. Uncertainties in specified greenhouse gases, aerosols emissions, land use change, etc. will all affect model results and hence evaluation of model quality. Different statistical methods used in model evaluation can also lead to subtle or substantive differences in the assessment of model quality.

9.6 Downscaling and Simulation of Regional-Scale Climate

Regional-scale climate information can be obtained directly from global models; however, their horizontal resolution is often too low to resolve features that are important at regional scales. High-resolution AGCMs, variable-resolution global models, and statistical and dynamical downscaling (i.e., regional climate modelling) are used to complement AOGCMs, and to generate region-specific climate information. These approaches are evaluated in the following.

9.6.1 Global Models

9.6.1.1 Regional-Scale Simulation by Atmosphere–Ocean General Circulation Models

A comparison of CMIP3 and CMIP5 seasonal cycles of temperature and precipitation for different regions (Figure 9.38) shows that temperature is generally better simulated than precipitation in terms of the amplitude and phase of the seasonal cycle. The multi-model mean is closer to observations than most of the individual models. The systematic difference between the CMIP5 and CMIP3 ensembles is small in most regions, although there is evident improvement in South Asia (SAS) and Tropical South America (TSA) in the rainy seasons. In some cases the spread amongst observational estimates can be of comparable magnitude to the model spread, e.g., winter in the Europe and Mediterranean (EUM) region.

There are as yet rather few published studies in which regional behaviour of the CMIP5 models is evaluated in great detail. Cattiaux et al. (2013) obtained results for Europe similar to those discussed above. Joetzjer et al. (2013) considered 13 models that participated in both CMIP3 and in CMIP5 and found that the seasonal cycle of precipitation over the Amazon improved in the latter.

Based on the CMIP archives, regional biases in seasonal and annual mean temperature and precipitation are shown for several land regions in Figure 9.39, and for polar and oceanic regions in Figure 9.40. The CMIP5 median temperature biases range from about –3°C to 1.5°C. Substantial cold biases over NH regions are more prevalent in winter (December to February) than summer (June to August). The median biases appear in most cases slightly less negative for CMIP5 than CMIP3. The spread amongst models, as characterized by the 25 to 75% and 5 to 95% ranges, is slightly reduced from CMIP3 to CMIP5 in a majority of the regions and is roughly ±3ºC. The RMS error of individual CMIP5 models is smaller than that for CMIP3 in 24 of the 26 regions in Figure 9.39 in DJF, JJA and the annual mean. The absolute value of the ensemble mean bias has also been reduced in most cases. The inter-model spread remains large, particularly in high-latitude regions in winter and in regions with steep orography (such as CAS, SAS, TIB and WSA). The inter-model temperature spread has decreased from CMIP3 to CMIP5 over most of the oceans and over the Arctic and Antarctic land regions. The cold winter bias over the Arctic has been reduced. There is little systematic inter-ensemble difference in temperature over lower latitude oceans.

Biases in seasonal total precipitation are shown in the right column of Figures 9.39 and 9.40 for the NH winter (October to March) and summer (April to September) half years as well as the annual mean. The largest systematic biases over land regions occur in ALA, WSA and TIB, where the annual precipitation exceeds that observed in all CMIP5 models, with a median bias on the order of 100%. All these regions are characterized by high orography and / or a large fraction of solid precipitation, both of which are expected to introduce a negative bias in gauge-based precipitation (Yang and Ohata, 2001; Adam et al., 2006) that may amplify the model-observation discrepancy. A large negative relative bias in SAH occurs in October to March, but it is of negligible magnitude in absolute terms. In nearly all other seasonal and regional cases over land, the observational estimate falls within the range of the CMIP5 simulations. Compared with CMIP3, the CMIP5 median precipitation is slightly higher in most regions. In contrast with temperature, the seasonal and annual mean ensemble mean and the root-mean square precipitation biases are larger for CMIP5 than for CMIP3 in a slight majority of land regions (Figure 9.39) and in most of the

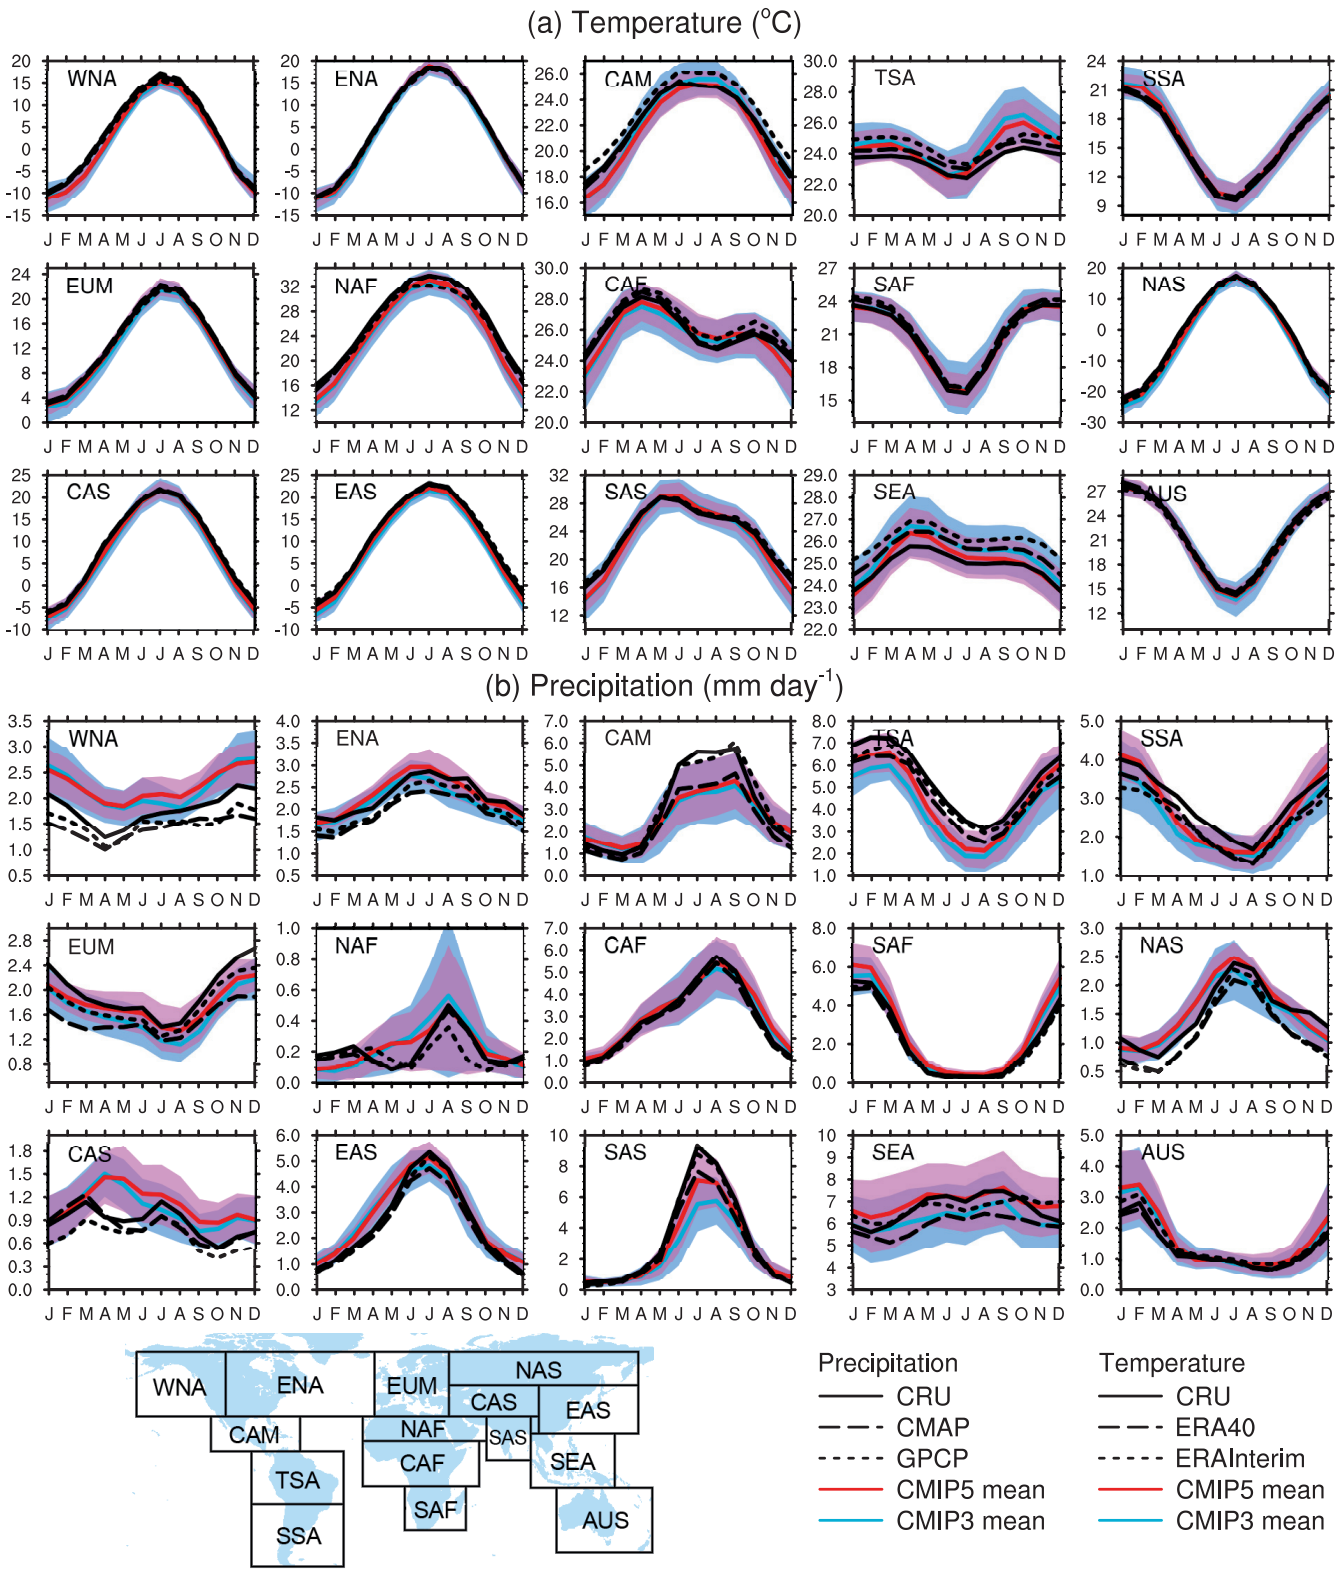

Figure 9.38 | Mean seasonal cycle of (a) temperature (°C) and (b) precipitation (mm day^{-1}). The average is taken over land areas within the indicated regions, and over the period 1980–1999. The red line is the average over 45 CMIP5 models; the blue line is the average over 22 CMIP3 models. The standard deviation of the respective data set is indicated with shading. The different line styles in black refer to observational and reanalysis data: Climatic Research Unit (CRU) TS3.10, ECMWF 40-year reanalysis (ERA40) and ERA-Interim for temperature; CRU TS3.10.1, Global Precipitation Climatology Project (GPCP), and CPC Merged Analysis of Precipitation (CMAP) for precipitation. Note the different axis-ranges for some of the sub-plots. The 15 regions shown are: Western North America (WNA), Eastern North America (ENA), Central America (CAM), Tropical South America (TSA), Southern South America (SSA), Europe and Mediterranean (EUM), North Africa (NAF), Central Africa (CAF), South Africa (SAF), North Asia (NAS), Central Asia (CAS), East Asia (EAS), South Asia (SAS), Southeast Asia (SEA) and Australia (AUS).

14 other regions (Figure 9.40). However, considering the observational uncertainty, the performance of the CMIP3 and CMIP5 ensembles is assessed to be broadly similar. The inter-model spreads are similar and typically largest in arid areas when expressed in relative terms.

Especially over the oceans and polar regions (Figure 9.40), the scarcity of observations and their uncertainty complicates the evaluation of simulated precipitation. Of two commonly used data sets, CMAP indicates systematically more precipitation than GPCP over low-latitude

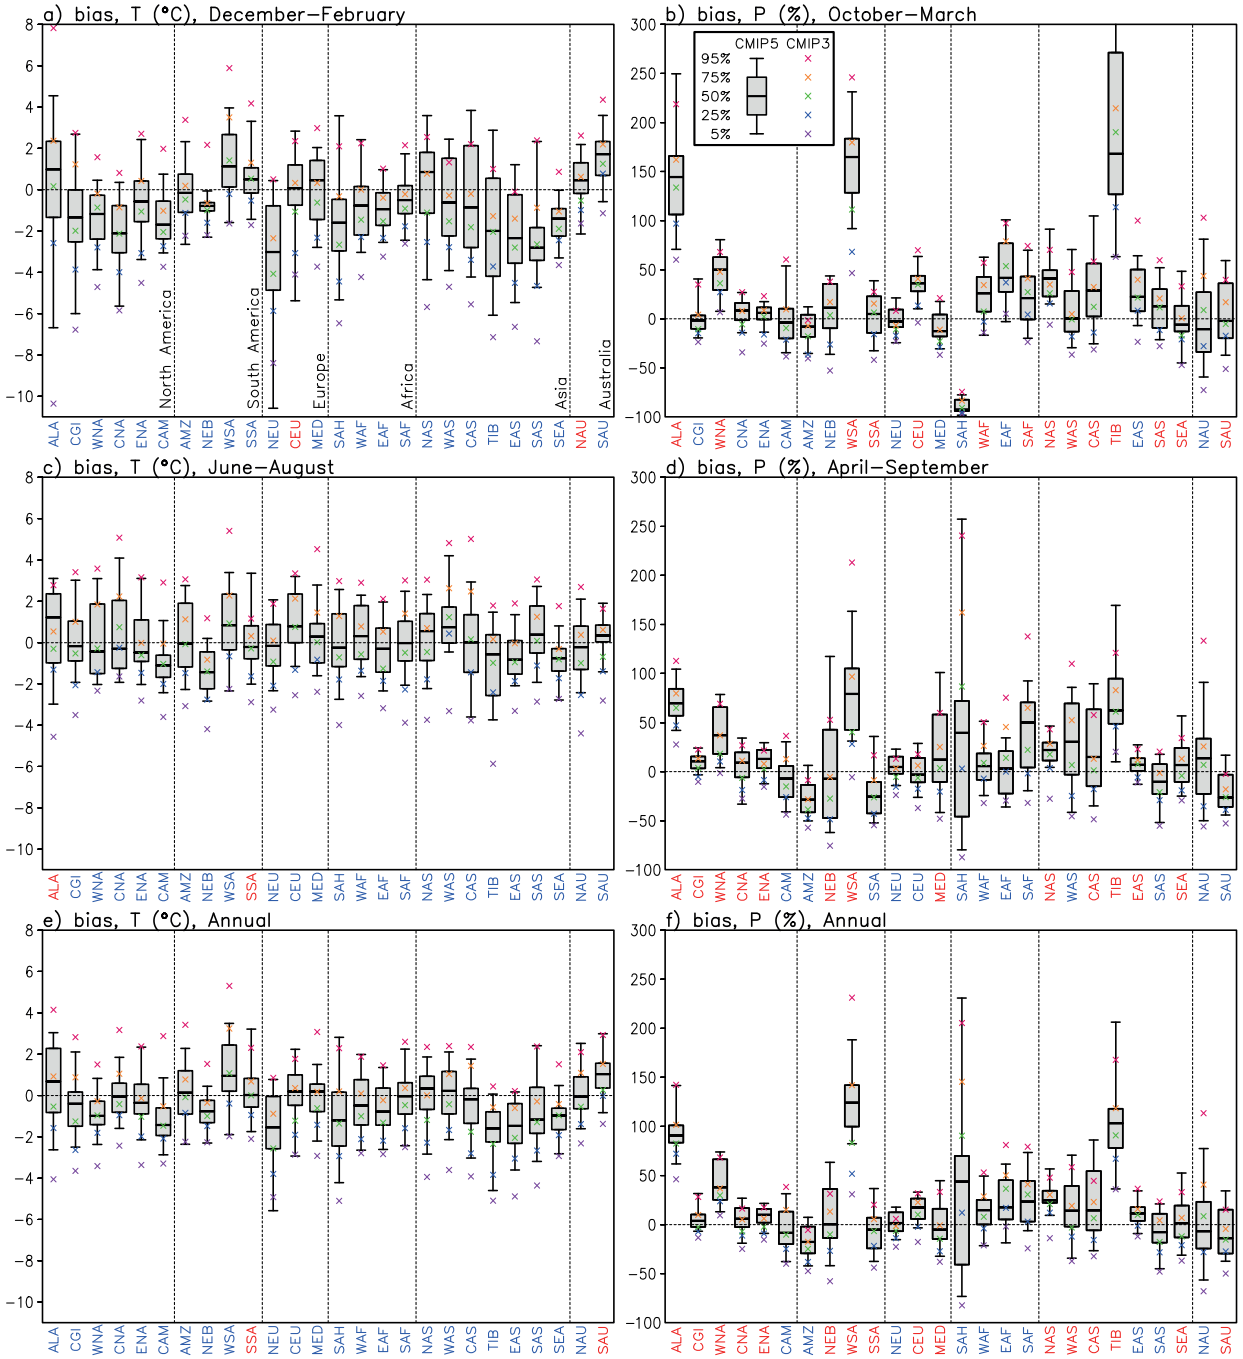

Figure 9.39 | Seasonal- and annual mean biases of (left) temperature (°C) and (right) precipitation (%) in the IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX) land regions (cf. Seneviratne et al., 2012, p. 12. The region's coordinates can be found from their online Appendix 3.A). The 5th, 25th, 50th, 75th and 95th percentiles of the biases in 42 CMIP5 models are shown in box-and-whisker format, and corresponding values for 23 CMIP3 models with crosses. The CMIP3 20C3M simulations are complemented with the corresponding A1B runs for the 2001–2005 period. The biases are calculated over 1986–2005, using Climatic Research Unit (CRU) T3.10 as the reference for temperature and CRU TS 3.10.01 for precipitation. The regions are labelled with red when the root-mean-square error for the individual CMIP5 models is larger than that for CMIP3 and blue when it is smaller. The regions are: Alaska/NW Canada (ALA), Eastern Canada/Greenland/Iceland (CGI), Western North America (WNA), Central North America (CNA), Eastern North America (ENA), Central America/Mexico (CAM), Amazon (AMZ), NE Brazil (NEB), West Coast South America (WSA), South-Eastern South America (SSA), Northern Europe (NEU), Central Europe (CEU), Southern Europe/the Mediterranean (MED), Sahara (SAH), Western Africa (WAF), Eastern Africa (EAF), Southern Africa (SAF), Northern Asia (NAS), Western Asia (WAS), Central Asia (CAS), Tibetan Plateau (TIB), Eastern Asia (EAS), Southern Asia (SAS), Southeast Asia (SEA), Northern Australia (NAS) and Southern Australia/New Zealand (SAU). Note that the region WSA is poorly resolved in the models.

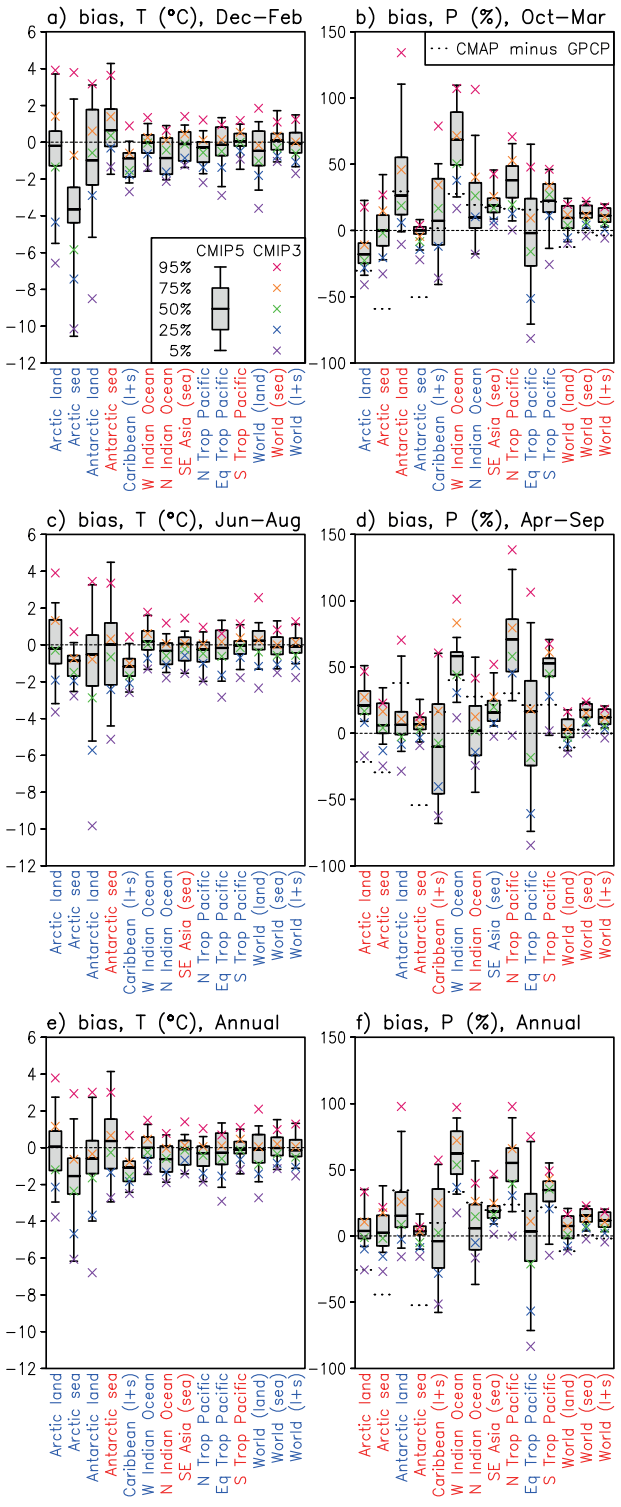

Figure 9.40 | As Figure 9.39, but for polar and ocean regions, with ECMWF reanalysis of the global atmosphere and surface conditions (ERA)-Interim reanalysis as the reference for temperature and Global Precipitation Climatology Project (GPCP) for precipitation. Global land, ocean and overall means are also shown. The regions are: Arctic: 67.5 to 90°N, Caribbean (area defined by the following coordinates): 68.8°W, 11.4°N; 85.8°W, 25°N; 60°W, 25°N, 60°W, 11.44°N; Western Indian Ocean: 25°S to 5°N, 52°E to 75°E; Northern Indian Ocean: 5°N to 30°N, 60°E to 95°E; Northern Tropical Pacific: 5°N to 25°N, 155°E to 150°W; Equatorial Tropical Pacific: 5°S to 5°N, 155°E to 130°W; Southern Tropical Pacific: 5°S to 25°S, 155°E to 130°W; Antarctic: 50°S to 90°S. The normalized difference between CPC Merged Analysis of Precipitation (CMAP) and GPCP precipitation is shown with dotted lines.

oceans and less over many high-latitude regions (Yin et al., 2004; Shin et al., 2011). Over most low-latitude ocean regions, annual precipitation in most CMIP3 and CMIP5 models exceeds GPCP. The difference relative to CMAP is smaller although mostly of the same sign. In Arctic and Antarctic Ocean areas, simulated precipitation is much above CMAP, but more similar to GPCP. Over Antarctic land, precipitation in most models is below CMAP, but close to or above GPCP.

Continental to sub-continental mean values may not be representative for smaller-scale biases, as biases generally increase with decreasing spatial averaging (Masson and Knutti, 2011b; Raisanen and Ylhaisi, 2011). A typical order of magnitude for grid-box-scale annual mean biases in individual CMIP3 models was 2°C for temperature and 1 mm day^{-1} for precipitation (Raisanen, 2007; Masson and Knutti, 2011b), with some geographical variation. This has been noted also in studies on how much spatial averaging would be needed in order to filter out the most unreliable small-scale features (e.g., Räisänen and Ylhäisi, 2011). In order to reduce such errors while still retaining information on small scales, Masson and Knutti (2011b) found, depending on the variable and the region, that smoothing needed to vary from the grid-point scale to around 2000 km.

On the whole, based on analysis of both ensemble means and inter-model spread, there is *high confidence* that the CMIP5 models simulate regional-scale temperature distributions somewhat better than the CMIP3 models did. This improvement is evident for most regions. For precipitation, there is *medium confidence* that there is no systematic change in model performance. In many regions, precipitation biases relative to CRU TS 3.10.01 and GPCP (and CMAP) are larger for CMIP5 than for CMIP3, but given observational uncertainty, the two ensembles are broadly similar.

9.6.1.2 Regional-Scale Simulation by Atmospheric General Circulation Models

Stand-alone global atmospheric models (AGCMs) run at higher resolution than AOGCMs provide complementary regional-scale climate information, sometimes referred to as 'global downscaling'. One important example of this is the simulation of tropical cyclones (e.g., Zhao et al., 2009, 2012; Murakami and Sugi, 2010; Murakami et al., 2012). A number of advantages of high-resolution AGCMs have been identified, including improved regional precipitation (Zhao et al., 2009; Kusunoki et al., 2011) and blocking (Matsueda et al., 2009, 2010). As AGCMs do not simulate interactions with the ocean, their ability to capture some high-resolution phenomena, such as the cold wake in the surface ocean after a tropical cyclone, is limited (e.g., Hasegawa and Emori, 2007). As in lower-resolution models, performance is affected by the quality of physical parameterizations (Lin et al., 2012; Mizuta et al., 2012; Zhao et al., 2012).

9.6.1.3 Regional-Scale Simulation by Variable-Resolution Global Climate Models

An alternative to global high resolution is the use of variable resolution (so-called 'stretched grid') models with higher resolution over the region of interest. Some examples are Abiodun et al. (2011) who showed that such simulations improve the simulation of West African

monsoon systems and African easterly jets, and White et al. (2013) who demonstrated improvements in temperature and precipitation related extreme indices. Fox-Rabinovitz et al. (2008) showed that regional biases in the high-resolution portion of a stretched grid model were similar to that of a global model with the same high resolution everywhere. Markovic et al. (2010) and Déqué (2010) reported similar results. Although not widely used, such methods can complement more conventional climate models.

9.6.2 Regional Climate Downscaling

Regional Climate Models (RCMs) are applied over a limited-area domain with boundary conditions either from global reanalyses or global climate model output. The use of RCMs for 'dynamical downscaling' has grown since the AR4, their resolution has increased, process-descriptions have developed further, new components have been added, and coordinated experimentation has become more widespread (Laprise, 2008; Rummukainen, 2010). Statistical downscaling (SD) involves deriving empirical relationships linking large-scale atmospheric variables (predictors) and local/regional climate variables (predictands). These relationships may then be applied to equivalent predictors from global models. SD methods have also been applied to RCM output (e.g., Boe et al., 2007; Déqué, 2007; Segui et al., 2010; Paeth, 2011; van Vliet et al., 2011). A significant constraint in a comprehensive evaluation of regional downscaling is that available studies often involve different methods, regions, periods and observational data for evaluation. Thus, evaluation results are difficult to generalize.

9.6.2.1 Recent Developments of Statistical Methods

The development of SD since the AR4 has been quite vigorous (e.g., Fowler et al., 2007; Maraun et al., 2010b), and many state-of-the-art approaches combine different methods (e.g., Vrac and Naveau, 2008; van Vliet et al., 2011). There is an increasing number of studies on extremes (e.g., Vrac and Naveau, 2008; Wang and Zhang, 2008), and on features such as hurricanes (Emanuel et al., 2008), river flow and discharge, sediment, soil erosion and crop yields (e.g., Zhang, 2007; Prudhomme and Davies, 2009; Lewis and Lamoureux, 2010). Techniques have also been developed to consider multiple climatic variables simultaneously in order to preserve some physical consistency (e.g., Zhang and Georgakakos, 2011). The methods used to evaluate SD approaches vary with the downscaled variable and include metrics related to intensities (e.g., Ning et al., 2011; Tryhorn and DeGaetano, 2011), temporal behaviour (e.g., May, 2007; Timbal and Jones, 2008; Maraun et al., 2010a; Brands et al., 2011), and physical processes (Lenderink and Van Meijgaard, 2008; Maraun et al., 2010a). SD capabilities are also examined through secondary variables like runoff, river discharge and stream flow (e.g., Boe et al., 2007; Teutschbein et al., 2011).

9.6.2.2 Recent Developments of Dynamical Methods

Since the AR4, typical RCM resolution has increased from around 50 km to around 25 km (e.g., Christensen et al., 2010). Long RCM runs at very high resolution are still, however, rather few (e.g., Yasutaka et al., 2008; Chan et al., 2012; Kendon et al., 2012). Coupled RCMs, with interactive ocean and, when appropriate, also sea ice have also been developed (Somot et al., 2008; Dorn et al., 2009; Artale et al., 2010; Doscher et al., 2010). Smith et al. (2011a) added vegetation dynamics–ecosystem biogeochemistry in an RCM.

At the time of the AR4, RCMs were typically used for time-slice experiments. Since then, multi-decadal and centennial RCM simulations have emerged in larger numbers (e.g., Diffenbaugh et al., 2011; Kjellstrom et al., 2011; de Elia et al., 2013). Coordinated RCM experiments and ensembles have also become much more common and today, with domains covering Europe (e.g., Christensen et al., 2010; Vautard et al., 2013), North America (e.g., Gutowski et al., 2010; Lucas-Picher et al., 2012a; Mearns et al., 2012), South America (e.g., Menendez et al., 2010; Chou et al., 2012; Krüger et al., 2012), Africa (e.g., Druyan et al., 2010; Ruti et al., 2011; Nikulin et al., 2012; Paeth et al., 2012; Hernández-Díaz et al., 2013), the Arctic (e.g., Inoue et al., 2006) and Asian regions (e.g., Feng and Fu, 2006; Shkolnik et al., 2007; Feng et al., 2011; Ozturk et al., 2012; Suh et al., 2012).

9.6.3 Skill of Downscaling Methods

Downscaling skill varies with location, season, parameter and boundary conditions (see Section 9.6.5) (e.g., Schmidli et al., 2007; Maurer and Hidalgo, 2008). Although there are indications that model skill increases with higher resolution, it does not do so linearly. Rojas (2006) found more improvement when increasing resolution from 135 km to 45 km than from 45 km to 15 km. Walther et al. (2013) found that the diurnal precipitation cycle and light precipitation improved more when going from 12 km to 6 km resolution than when going from 50 km to 25 km or from 25 km to 12 km. Higher resolution does enable better simulation of extremes (Seneviratne et al., 2012). For example, Pryor et al. (2012) noted that an increase in RCM resolution from 50 km to 6 km increased extreme wind speeds more than the mean wind speed. Kawazoe and Gutowski (2013) compared six RCMs and the two GCMs to high resolution observations, concluding that precipitation extremes were more representative in the RCMs than in the GCMs. Vautard et al. (2013) found that warm extremes in Europe were generally better simulated in RCMs with 12 km resolution compared to 50 km. Kendon et al. (2012) and Chan et al. (2012) found mixed results in daily precipitation simulated at 12 km and 1.5 km resolution, although the latter had improved sub-daily features, perhaps as convection could be explicitly resolved.

Coupled RCMs, with an interactive ocean, offer further improvements. Döscher et al. (2010) reproduced empirical relationships between Arctic sea ice extent and sea ice thickness and NAO in a coupled RCM. Zou and Zhou (2013) found that a regional ocean–atmosphere model improved the simulation of precipitation over the western North Pacific compared to an uncoupled model. Samuelsson et al. (2010) showed that coupling a lake model with an RCM captured the effect of lakes on the air temperature over adjacent land. Lenaerts et al. (2012) added drifting snow in an RCM run for the Antarctica, which increased the area of ablation and improved the fit to observations. Smith et al. (2011a) added vegetation dynamics–ecosystem biogeochemistry into an RCM, and found some evidence of local feedback to air temperature.

Applying an RCM developed for a specific region to other regions exposes it to a wider range of conditions and therefore provides an

opportunity for more rigorous evaluation. Transferability experiments target this by running RCMs for different regions while holding their process-descriptions constant (cf. Takle et al., 2007; Gbobaniyi et al., 2011; Jacob et al., 2012). Suh et al. (2012) noted that 10 RCMs run for Africa did well overall for average and maximum temperature, but systematically overestimated the daily minimum temperature. Precipitation was generally simulated betted for wet regions than for dry regions. Similarly, Nikulin et al. (2012) reported on 10 RCMs over Africa, run with boundary conditions from ERA-Interim, and evaluated against different observational data sets. Many of the RCMs simulated precipitation better than the ERA-Interim reanalysis itself.

Christensen et al. (2010) examined a range metrics related to simulation of extremes, mesoscale features, trends, aspects of variability and consistency with the driving boundary conditions. Only one of these metrics led to clear differentiation among RCMs (Lenderink, 2010). This may imply a general skilfulness of models, but may also simply indicate that the metrics were not very informative. Nevertheless, using some of these metrics, Coppola et al. (2010) and Kjellström et al. (2010) found that weighted sets of RCMs outperformed sets without weighting for both temperature and precipitation. Sobolowski and Pavelsky (2012) demonstrated a similar impact.

9.6.4 Value Added through RCMs

RCMs are regularly tested to evaluate whether they show improvements over global models (Laprise et al., 2008), that is, whether they do indeed 'add value'. In essence, added value is a measure of the extent to which the downscaled climate is closer to observations than the model from which the boundary conditions were obtained. Differences between RCM and GCM simulations are not always very obvious for time-averaged quantities on larger scales or in fairly homogeneous regions. RCM fields are, however, richer in spatial and temporal detail. Indeed, the added value of RCMs is mainly expected in the simulation of topography-influenced phenomena and extremes with relatively small spatial or short temporal character (e.g., Feser et al., 2011; Feser and Barcikowska, 2012; Shkol'nik et al., 2012). As an example, RCM downscaling led to better large-scale monsoon precipitation patterns (Gao et al., 2012) for East Asia than in the global models used for boundary conditions. In the few instances where RCMs have been interactively coupled to global models (i.e., 'two-way' coupling), the effects of improved small scales propagate to larger scales and this has been found to improve the simulation of larger scale phenomena (Lorenz and Jacob, 2005; Inatsu and Kimoto, 2009; Inatsu et al., 2012).

Other examples include improved simulation of convective precipitation (Rauscher et al., 2010), near-surface temperature (Feser, 2006), near-surface temperature and wind (Kanamaru and Kanamitsu, 2007), temperature and precipitation (Lucas-Picher et al., 2012b), extreme precipitation (Kanada et al., 2008), coastal climate features (Winterfeldt and Weisse, 2009; Winterfeldt et al., 2011; Kawazoe and Gutowski, 2013; Vautard et al., 2013), Atlantic hurricanes (Bender et al., 2010), European storm damage (Donat et al., 2010), strong mesoscale cyclones (Cavicchia and Storch, 2011), cutoff lows (Grose et al., 2012), polar lows (Zahn and von Storch, 2008) and higher statistical moments of the water budget (e.g., Bresson and Laprise, 2011).

In summary, there is *high confidence* that downscaling adds value to the simulation of spatial climate detail in regions with highly variable topography (e.g., distinct orography, coastlines) and for mesoscale phenomena and extremes. Regional downscaling is therefore complementary to results obtained directly from global climate models. These results are from a variety of distinct studies with different RCMs.

9.6.5 Sources of Model Errors and Uncertainties

In addition to issues related to resolution and model complexity (see Section 9.6.3), errors and uncertainties arise from observational uncertainty in evaluation data and parameterizations (see Box 9.3), choice of model domain and application of boundary conditions (driving data).

In the case of SD, sources of model errors and uncertainties depend on the choice of method, including the choice of the predictors, the estimation of empirical relationships between predictors and predictands from limited data sets, and also the data used to estimate the predictors (Frost et al., 2011). There are numerous different SD methods, and the findings are difficult to generalize.

Small domains allow less freedom for RCMs to generate the small-scale features that give rise to added value (e.g., Leduc and Laprise, 2009). Therefore large domains –covering entire continents– have become more common. Køltzow et al. (2008) found improvements with the use of a larger domain, but the RCM solution can become increasingly 'decoupled' from the driving data (e.g., Rockel et al., 2008), which can introduce inconsistencies. Large domains also introduce large internal variability, which can significantly contaminate interannual variability of seasonal means (Kanamitsu et al., 2010). Techniques such as spectral nudging (Misra, 2007; Separovic et al., 2012) can be used to constrain such inconsistencies (Feser et al., 2011). Winterfeldt and Weisse (2009) concluded that nudging improved the simulation of marine wind climate, while Otte et al. (2012) demonstrated improvements in temperature and precipitation. Nudging may, however, also lead to deterioration of features such as precipitation extremes (Alexandru et al., 2009; Kawazoe and Gutowski, 2013). Veljovic et al. (2010) showed that an RCM can in fact improve the large scales with respect to those inherent in the boundary conditions, and argued that nudging may be undesirable.

The quality of RCM results may vary according to the synoptic situation, season, and the geographic location of the lateral boundaries (Alexandru et al., 2007; Xue et al., 2007; Laprise et al., 2008; Separovic et al., 2008; Leduc and Laprise, 2009; Nikiema and Laprise, 2010; Rapaić et al., 2010). In addition to lateral boundary conditions, RCMs also need sea surface information. Few studies have explored the dependency of RCM results on the treatment of the SSTs and sea ice, although Koltzow et al. (2011) found that the specification of SSTs was less influential than was the domain or the lateral boundaries. Woollings et al. (2010a) investigated the effect of specified SST on the simulation of the Atlantic storm track and found that it was better simulated with high-resolution SSTs, whereas increasing temporal resolution gave mixed results.

As is the case in global models, RCM errors are directly related to shortcomings in process parameterizations. Examples include the

representation of clouds, convection and land surface–atmosphere interactions, the planetary boundary layer, horizontal diffusion, and microphysics (Tjernstrom et al., 2008; Wyser et al., 2008; Lynn et al., 2009; Pfeiffer and Zängl, 2010; Axelsson et al., 2011; Crétat et al., 2012; Evans et al., 2012; Roy et al., 2012; Solman and Pessacg, 2012). The representation of land surface and atmosphere coupling is also important, particularly for simulating monsoon regions (Cha et al., 2008; Yhang and Hong, 2008; Boone et al., 2010; Druyan et al., 2010; van den Hurk and van Meijgaard, 2010).

9.6.6 Relating Downscaling Performance to Credibility of Regional Climate Information

A fundamental issue is how the performance of a downscaling method relates to its ability to provide credible future projections (Raisanen, 2007). This subject is discussed further in Section 9.8. The credibility of downscaled information of course depends on the quality of the downscaling method itself (e.g., Dawson et al., 2012; Déqué et al., 2012; Eum et al., 2012), and on the quality of the global climate models providing the large-scale boundary conditions (e.g., van Oldenborgh et al., 2009; Diaconescu and Laprise, 2013).

Specific to SD is the statistical stationarity hypothesis, that is, that the relationships inferred from historical data remain valid under a changing climate (Maraun, 2012). Vecchi et al. (2008) note that a statistical method that captures interannual hurricane variability gives very different results for projections compared to RCMs. Such results suggest that good performance of statistical downscaling as assessed against observations does not guarantee credible regional climate information. Some recent studies have proposed ways to evaluate SD approaches using RCM outputs (e.g., Vrac and Naveau, 2008; Driouech et al., 2010) or long series of observations (e.g. Schmith, 2008).

Giorgi and Coppola (2010) argued that regional-scale climate projections over land in the CMIP3 models were not sensitive to their temperature biases. For precipitation, the same was found for about two thirds of the global land area. However, there is some recent evidence that regional biases may be nonlinear for temperature extremes (Christensen et al., 2008; Boberg and Christensen, 2012; Christensen and Boberg, 2013) in both global and regional models. A mechanism at play may be that models tend to dry out the soil too effectively at high temperatures, which can lead to systematic biases in projected warm summertime conditions (Christensen et al., 2008; Kostopoulou et al., 2009). This is illustrated in Figure 9.41 for the Mediterranean region, which suggests a tendency in RCMs, CMIP3 and CMIP5 models towards an enhanced warm bias in the warmer months. The implication is that the typically large warming signal in these regions could be biased (Boberg and Christensen, 2012; Mearns et al., 2012). Findings such as these stress the importance of a thorough assessment of models' biases when they are applied for projections (e.g., de Elia and Cote, 2010; Boberg and Christensen, 2012; Christensen and Boberg, 2013).

Di Luca et al. (2012) analysed downscaled climate change projections from six RCMs run over North America. The climate change signals for seasonal precipitation and temperature were similar to those in the driving AOGCMs, and the spatial detail gained by downscaling was comparable in both present and future climate. Déqué et al. (2012) studied projections with several combinations of AOGCM and RCM for Europe. A larger part of the spread in winter temperature and

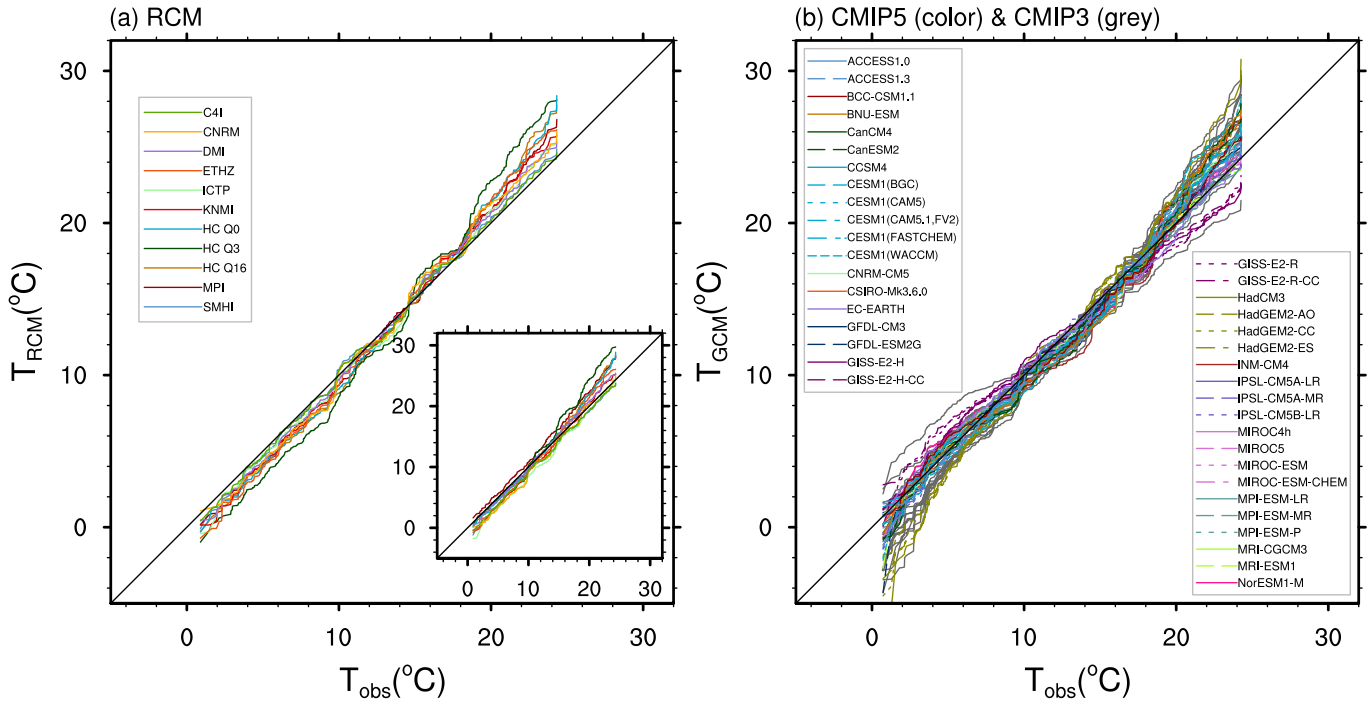

Figure 9.41 | Ranked modelled versus observed monthly mean temperature for the Mediterranean region for the 1961–2000 period. The Regional Climate Model (RCM) data (a) are from Christensen et al. (2008) and are adjusted to get a zero mean in model temperature with respect to the diagonal. The smaller insert shows uncentred data. The General Circulation Model (GCM) data (b) are from CMIP5 and CMIP3 and adjusted in the same way. (After Boberg and Christensen, 2012.)

precipitation projections was explained by the differences in global model boundary conditions, although much of the spread in projected summer precipitation was explained by RCM. This underlines the importance of both the quality of the boundary conditions and the downscaling method.

9.7 Climate Sensitivity and Climate Feedbacks

An overall assessment of climate sensitivity and transient climate response is given in Box 12.2. Observational constraints based on observed warming over the last century are discussed in Section 10.8.2 and shown in Box 12.2, Figure 2.

9.7.1 Equilibrium Climate Sensitivity, Idealized Radiative Forcing, and Transient Climate Response in the Coupled Model Intercomparison Project Phase 5 Ensemble

Equilibrium climate sensitivity (ECS) is the equilibrium change in global and annual mean surface air temperature after doubling the atmospheric concentration of CO_2 relative to pre-industrial levels. In the AR4, the range in equilibrium climate sensitivity of the CMIP3 models was 2.1°C to 4.4°C, and the single largest contributor to this spread was differences among modelled cloud feedbacks. These assessments carry over to the CMIP5 ensemble without any substantial change (Table 9.5).

The method of diagnosing climate sensitivity in CMIP5 differs fundamentally from the method employed in CMIP3 and assessed in the AR4 (Randall et al., 2007). In CMIP3, an AGCM was coupled to a non-dynamic mixed-layer (slab) ocean model with prescribed ocean heat transport convergence. CO_2 concentration was then instantaneously doubled, and the model was integrated to a new equilibrium with unchanged implied ocean heat transport. While computationally efficient, this method had the disadvantage of employing a different model from that used for the historical simulations and climate projections. However, in the few comparisons that were made, the resulting disagreement in ECS was less than about 10% (Boer and Yu, 2003; Williams et al., 2008; Danabasoglu and Gent, 2009; Li et al., 2013a). In CMIP5, climate sensitivity is diagnosed directly from the AOGCMs following the approach of Gregory et al. (2004). In this case the CO_2 concentration is instantaneously quadrupled and kept constant for 150 years of simulation, and both equilibrium climate sensitivity and RF are diagnosed from a linear fit of perturbations in global mean surface temperature to the instantaneous radiative imbalance at the TOA.

The transient climate response (TCR) is the change in global and annual mean surface temperature from an experiment in which the CO_2 concentration is increased by 1% yr^{-1}, and calculated using the difference between the start of the experiment and a 20-year period centred on the time of CO_2 doubling. TCR is smaller than ECS because ocean heat uptake delays surface warming. TCR is linearly correlated with ECS in the CMIP5 ensemble (Figure 9.42), although the relationship may be nonlinear outside the range spanned in Table 9.5 (Knutti et al., 2005).

Based on the methods outlined above and explained in Section 9.7.2 below, Table 9.5 shows effective ERF, ECS, TCR and feedback strengths for the CMIP5 ensemble. The two estimates of ERF agree with each other to within 5% for six models (CanESM2, INM-CM4, IPSL-CM5A-LR, MIROC5, MPI-ESM-LR and MPI-ESM-P), although the deviation exceeds 10% for four models (CCSM4, CSIRO-Mk3-6-0, HadGEM2-ES, and MRI-CGCM3) and is indicative of deviations from the basic assumptions underlying one or both ERF estimation methods. However, the mean difference of 0.3 W m^{-2} between the two methods for diagnosing ERF is only about half of the ensemble standard deviation of 0.5 W m^{-2}, or 15% of the mean value for ERF by CO_2 using fixed SSTs. ECS and TCR vary across the ensemble by a factor of approximately 2. The multi-model ensemble mean in ECS is 3.2°C, a value nearly identical to that for CMIP3, while the CMIP5 ensemble range is 2.1°C to 4.7°C, a spread which is also nearly indistinguishable from that for CMIP3. While every CMIP5 model whose heritage can

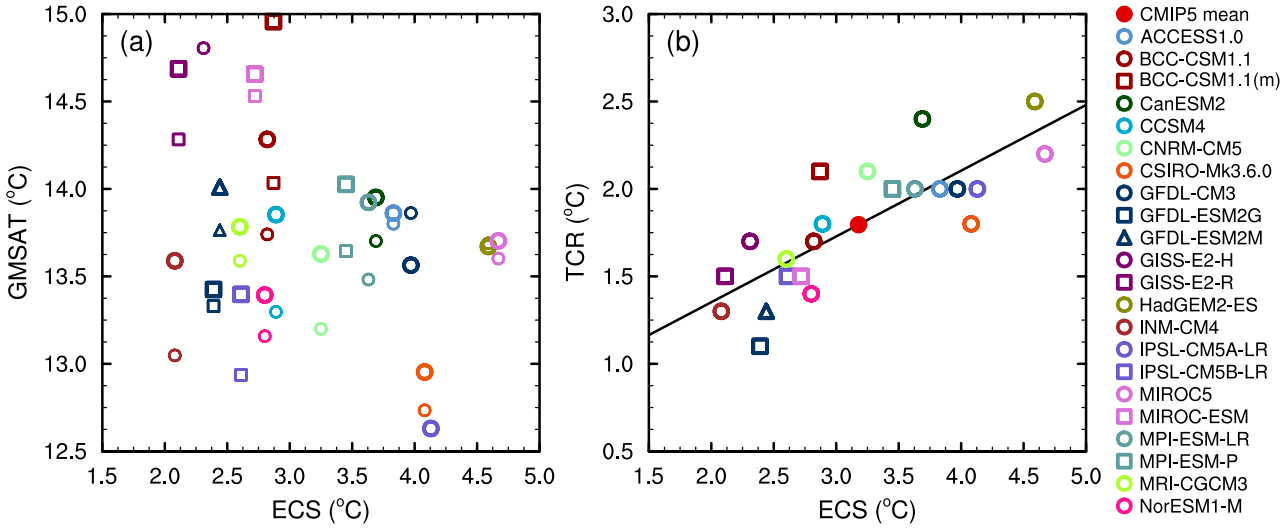

Figure 9.42 | (a) Equilibrium climate sensitivity (ECS) against the global mean surface temperature of CMIP5 models, both for the period 1961–1990 (larger symbols, cf. Figure 9.8, Table 9.5) and for the pre-industrial control runs (smaller symbols). (b) Equilibrium climate sensitivity against transient climate response (TCR). The ECS and TCR information are based on Andrews et al. (2012) and Forster et al. (2013) and updated from the CMIP5 archive.

Table 9.5 | Effective radiative forcing (ERF), climate sensitivity and climate feedbacks estimated for the CMIP5 AOGCMs (see Table 9.1 for model details). ERF, equilibrium climate sensitivity (ECS) and transient climate response (TCR) are based on Andrews et al. (2012) and Forster et al. (2013) and updated from the CMIP5 archive. The ERF entries are calculated according to Hansen et al. (2005) using fixed sea surface temperatures (SSTs) and Gregory et al. (2004) using regression. ECS is calculated using regressions following Gregory et al. (2004). TCR is calculated from the CMIP5 simulations with 1% CO_2 increase per year (Taylor et al., 2012b), using the 20-year mean centred on the year of CO_2 doubling. The climate sensitivity parameter and its inverse, the climate feedback parameter, are calculated from the regression-based ERF and the ECS. Strengths of the individual feedbacks are taken from Vial et al. (2013), following Soden et al. (2008) and using radiative kernel methods with two different kernels. The sign convention is such that a positive entry for an individual feedback marks a positive feedback; the sum of individual feedback strengths must hence be multiplied by –1 to make it comparable to the climate feedback parameter. The entries for radiative forcing and equilibrium climate sensitivity were obtained by dividing by two the original results, which were obtained for CO_2 quadrupling. ERF and ECS for BNU-ESM are from Vial et al. (2013).

Model	Effective Radiative Forcing $2 \times CO_2$ (W m^{-2})		Equilibrium Climate Sensitivity (°C)	Transient Climate Response (°C)	Climate Sensitivity Parameter (°C (W m^{-2})$^{-1}$)	Climate Feedback Parameter (W m^{-2} °C^{-1})	Planck Feedback (W m^{-2} °C^{-1})	Water Vapour Feedback (W m^{-2} °C^{-1})	Lapse Rate Feedback (W m^{-2} °C^{-1})	Surface Albedo Feedback (W m^{-2} °C^{-1})	Cloud Feedback (W m^{-2} °C^{-1})

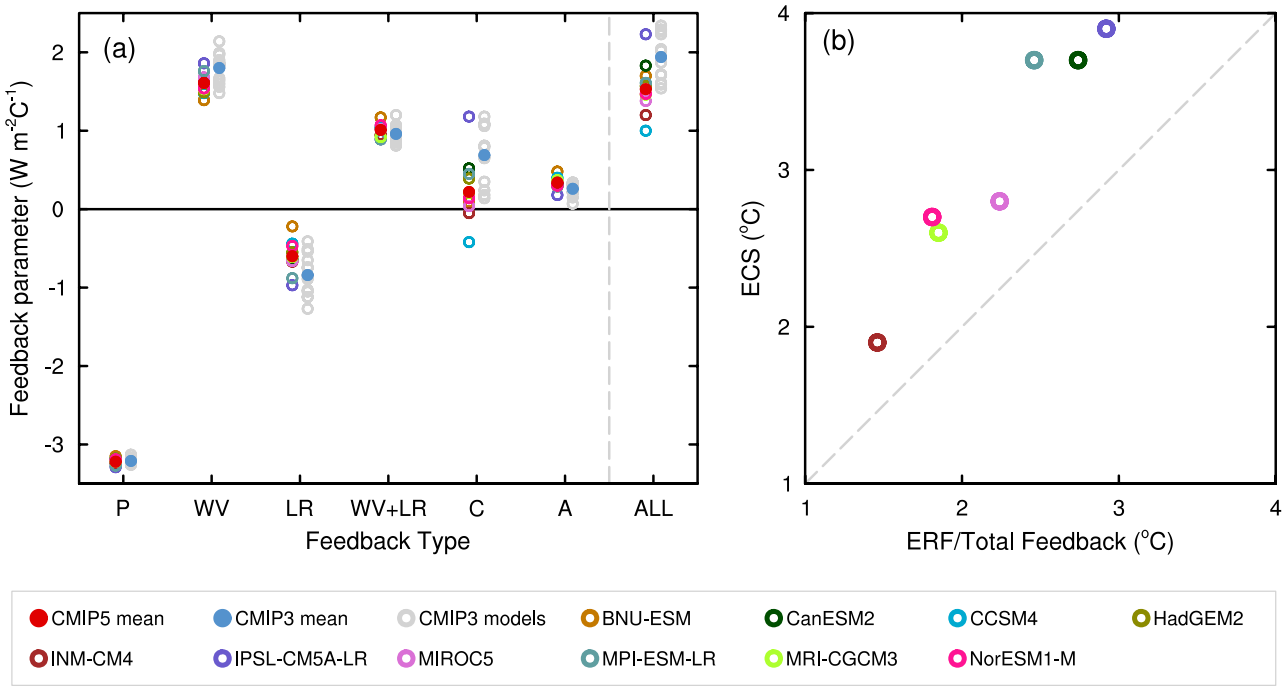

Figure 9.43 | (a) Strengths of individual feedbacks for CMIP3 and CMIP5 models (left and right columns of symbols) for Planck (P), water vapour (WV), clouds (C), albedo (A), lapse rate (LR), combination of water vapour and lapse rate (WV+LR) and sum of all feedbacks except Planck (ALL), from Soden and Held (2006) and Vial et al. (2013), following Soden et al. (2008). CMIP5 feedbacks are derived from CMIP5 simulations for abrupt fourfold increases in CO_2 concentrations ($4 \times CO_2$). (b) ECS obtained using regression techniques by Andrews et al. (2012) against ECS estimated from the ratio of CO_2 ERF to the sum of all feedbacks. The CO_2 ERF is one-half the $4 \times CO_2$ forcings from Andrews et al. (2012), and the total feedback (ALL + Planck) is from Vial et al. (2013).

be traced to CMIP3 shows some change in ECS, there is no discernible systematic tendency. This broad similarity between CMIP3 and CMIP5 and the good agreement between different methods where they were applied to the same atmospheric GCM indicate that the uncertainty in methodology is minor compared to the overall spread in ECS. The change in TCR from CMIP3 to CMIP5 is generally of the same sign but of smaller magnitude compared to the change in ECS. The relationship between ECS and an estimates derived from total feedbacks are discussed in Section 9.7.2.

Although ECS can vary with global mean surface temperature owing to the temperature dependencies of the various feedbacks (Colman and McAvaney, 2009; cf. Section 9.7.2), Figure 9.42 shows no discernible correlation for the CMIP5 historical temperature ranges, a fact that suggests that ECS is less sensitive to errors in the current climate than to other sources of uncertainty.

9.7.2 Understanding the Range in Model Climate Sensitivity: Climate Feedbacks

The strengths of individual feedbacks for the CMIP3 and CMIP5 models are compared in Figure 9.43. The feedbacks are generally similar between CMIP3 and CMIP5, and the water vapour, lapse rate, and cloud feedbacks are assessed in detail in Chapter 7. The surface albedo feedback is assessed here to be *likely* positive. There is *high confidence* that the sum of all feedbacks (excluding the Planck feedback) is positive. Advances in estimating and understanding each of the feedback parameters in Table 9.5 are described in detail below (see also Chapters 7 and 8).

9.7.2.1 Role of Humidity and Lapse Rate Feedbacks in Climate Sensitivity

The compensation between the water vapour and lapse-rate feedbacks noted in the CMIP3 models is still present in the CMIP5 models, and possible explanations of the compensation have been developed (Ingram, 2010; Ingram, 2013). New formulations of the feedbacks, replacing specific with relative humidity, eliminate most of the cancellation between the water vapour and lapse rate feedbacks and reduce the inter-model scatter in the individual feedback terms (Held and Shell, 2012).

9.7.2.2 Role of Surface Albedo in Climate Sensitivity

Analysis of observed declines in sea ice and snow coverage from 1979 to 2008 suggests that the NH albedo feedback is between 0.3 and 1.1 W m^{-2} °C^{-1} (Flanner et al., 2011). This range is substantially above the global feedback of 0.3 ± 0.1 W m^{-2} °C^{-1} of the CMIP5 models analysed in Table 9.5. One possible explanation is that the CMIP5 models underestimate the strength of the feedback as did the CMIP3 models based upon the systematic errors in simulated sea ice coverage decline relative to observed rates (Boe et al., 2009b).

9.7.2.3 Role of Cloud Feedbacks in Climate Sensitivity

Cloud feedbacks represent the main cause for the range in modelled climate sensitivity (Chapter 7). The spread due to inter-model differences in cloud feedbacks is approximately 3 times larger than the spread contributed by feedbacks due to variations in water vapour and lapse

rate combined (Dufresne and Bony, 2008), and is a primary factor governing the range of climate sensitivity across the CMIP3 ensemble (Volodin, 2008a). Differences in equilibrium and effective climate sensitivity are due primarily to differences in the shortwave cloud feedback (Yokohata et al., 2008).

In perturbed ensembles of three different models, the primary cloud-related factor contributing to the spread in equilibrium climate sensitivity is the low-level shortwave cloud feedback (Yokohata et al., 2010; Klocke et al., 2011). Changes in the high-altitude clouds also induce climate feedbacks due to the large areal extent and significant longwave cloud radiative effects of tropical convective cloud systems. In experiments with perturbed physics ensembles of AOGCMs, the parameterization of ice fall speed also emerges as one of the most important determinants of climate sensitivity (Sanderson et al., 2008a, 2010; Sexton et al., 2012). Other non-microphysical feedback mechanisms are detailed in Chapter 7.

Cloud feedbacks in AOGCMs are generally positive or near neutral (Shell et al., 2008; Soden et al., 2008), as evidenced by the net positive or neutral cloud feedbacks in all of the models examined in a multi-thousand member ensemble of AOGCMs constructed by parameter perturbations (Sanderson et al., 2010). The sign of cloud feedbacks in the current climate deduced from observed relationships between SSTs and TOA radiative fluxes are discussed further in Section 7.2.5.7.

9.7.2.4 Relationship of Feedbacks to Modelled Climate Sensitivity

The ECS can be estimated from the ratio of forcing to the total climate feedback parameter. This approach is applicable to simulations in which the net radiative balance is much smaller than the forcing and hence the modelled climate system is essentially in equilibrium. This approach can also serve to check the internal consistency of estimates of the ECS, forcing, and feedback parameters obtained using independent methods. The relationship between ECS from Andrews et al. (2012) and estimates of ECS obtained from the ratio of forcings to feedbacks is shown in Figure 9.43b. The forcings are estimated using both regression and fixed SST techniques (Gregory et al., 2004; Hansen et al., 2005) by Andrews et al. (2012) and the feedbacks are calculated using radiative kernels (Soden et al., 2008). On average, the ECS from forcing to feedback ratios underestimate the ECS from Andrews et al. (2012) by 25% and 35%, or up to 50% for individual models, using fixed-SST and regression forcings, respectively.

9.7.2.5 Relationship of Feedbacks to Uncertainty in Modelled Climate Sensitivity

Objective methods for perturbing uncertain model parameters to optimize performance relative to a set of observational metrics have shown a tendency toward an increase in the mean and a narrowing of the spread of estimated climate sensitivity (Jackson et al., 2008a). This tendency is opposed by the effects of structural biases related to incomplete process representations in GCMs. If common structural biases are replicated across models in a MME (cf. Section 9.2.2.7), the most likely sensitivity for the MME tends to shift towards lower sensitivities while the possibility of larger sensitivities increases at the same time (Lemoine, 2010). Following Schlesinger and Mitchell (1987), Roe and Baker (2007) suggest that symmetrically distributed uncertainties in feedbacks lead to inherently asymmetrical uncertainties in climate sensitivity with increased probability in extreme positive values of the sensitivity. Roe and Baker (2007) conclude that this relationship makes it extremely difficult to reduce uncertainties in climate sensitivity through incremental improvements in the specification of feedback parameters. While subsequent analysis has suggested that this finding could be an artifact of the statistical formulation (Hannart et al., 2009) and linearization (Zaliapin and Ghil, 2010) of the relationship between feedback and sensitivity adopted by (Roe and Baker, 2007), these issues remain unsettled (Roe and Armour, 2011; Roe and Baker, 2011).

9.7.3 Climate Sensitivity and Model Performance

Despite the range in equilibrium sensitivity of 2.1°C to 4.4°C for CMIP3 models, they reproduce the global surface air temperature anomaly of 0.76°C over 1850–2005 to within 25% relative error. The relatively small range of historical climate response suggests that there is another mechanism, for example a compensating non-GHG forcing, present in the historical simulations that counteracts the relatively large range in sensitivity obtained from idealized experiments forced only by increasing CO_2. One possible mechanism is a systematic negative correlation across the multi-model ensemble between ECS and anthropogenic aerosol forcing (Kiehl, 2007; Knutti, 2008; Anderson et al., 2010). A second possible mechanism is a systematic overestimate of the mixing between the oceanic mixed layer and the full depth ocean underneath (Hansen et al., 2011). However, despite the same range of ECS in the CMIP5 models as in the CMIP3 models, there is no significant relationship across the CMIP5 ensemble between ECS and the 20th-century ERF applied to each individual model (Forster et al., 2013). This indicates a lesser role of compensating ERF trends from GHGs and aerosols in CMIP5 historical simulations than in CMIP3. Differences in ocean heat uptake also do not appreciably affect the spread in projected changes in global mean temperature by 2095 (Forster et al., 2013).

9.7.3.1 Constraints on Climate Sensitivity from Earth System Models of Intermediate Complexity

An EMIC intercomparison (Eby et al., 2013; Zickfeld et al., 2013) allows an assessment of model response characteristics, including ECS, TCR, and heat uptake efficiency (Table 9.6). In addition, Bayesian methods applied to PPE experiments using EMICs have estimated uncertainty in model response characteristics (see Box 12.2) based on simulated climate change in 20th century, past millennia, and LGM scenarios. Here, the range of response metrics (Table 9.6) described for default model configurations (Eby et al., 2013) indicates consistency with the CMIP5 ensemble.

9.7.3.2 Climate Sensitivity During the Last Glacial Maximum

Climate sensitivity can also be explored in another climatic context. The AR4 assessed attempts to relate simulated LGM changes in tropical SST to global climate sensitivity (Hegerl et al., 2007; Knutti and Hegerl, 2008). LGM temperature changes in the tropics (Hargreaves et al., 2007), but not in Antarctica (Hargreaves et al., 2012), have been

Table 9.6 | Model response metrics for EMICs in Table 9.2. TCR_{2X}, TCR_{4X} and ECS_{4X} are the changes in global average model surface air temperature from the decades centred at years 70, 140 and 995 respectively, from the idealized 1% increase to 4 × CO_2 experiment. The ocean heat uptake efficiency, κ_{4X}, is calculated from the global average heat flux divided by TCR_{4X} for the decade centred at year 140, from the same idealized experiment. ECS_{2x} was calculated from the decade centred about year 995 from a 2 × CO_2 pulse experiment. (Data from Eby et al., 2013.)

shown to scale well with climate sensitivity because the signal is mostly dominated by CO_2 forcing in these regions (Braconnot et al., 2007b; Jansen et al., 2007). The analogy between the LGM climate sensitivity and future climate sensitivity is, however, not perfect (Crucifix, 2006). In a single-model ensemble of simulations, the magnitudes of the LGM cooling and the warming induced by a doubling of CO_2 are nonlinear in the forcings applied (Hargreaves et al., 2007). Differences in the cloud radiative feedback are at the origin of this asymmetric response to equivalent positive and negative forcings (Yoshimori et al., 2009). There is thus still *low confidence* that the regional LGM model-data comparisons can be used to evaluate model climate sensitivity. However, even if the results do not scale perfectly with equilibrium or transient climate sensitivity, the LGM simulations allow the identification of the different feedback factors that contributed to the LGM global cooling (Yoshimori et al., 2011) and model spread in these feedbacks. The largest spread in LGM model feedbacks is found for the shortwave cloud feedback, just as for the modern climate. This correspondence between LGM and modern climates adds to the *high confidence* that the shortwave cloud feedback is the dominant source of model spread in climate sensitivity (cf. Section 5.3.3).

9.7.3.3 Constraints on Equilibrium Climate Sensitivity from Climate-Model Ensembles and Observations

The large scale climatological information available has so far been insufficient to constrain model behaviour to a range tighter than CMIP3, at least on a global scale. Sanderson and Knutti (2012) suggest that much of the available and commonly used large scale observations have already been used to develop and evaluate models and are therefore of limited value to further constrain climate sensitivity or TCR. The assessed literature suggests that the range of climate sensitivities and transient responses covered by CMIP3/5 cannot be narrowed significantly by constraining the models with observations of the mean climate and variability, consistent with the difficulty of constraining the cloud feedbacks from observations (see Chapter 7). Studies based on PPE and CMIP3 support the conclusion that a credible representation of the mean climate and variability is very difficult to achieve with equilibrium climate sensitivities below 2°C (Piani et al., 2005; Stainforth et al., 2005; Sanderson et al., 2008a, 2008b; Huber et al., 2011; Klocke et al., 2011; Fasullo and Trenberth, 2012). High climate sensitivity values above 5°C (in some cases above 10°C) are found in the PPE based on HadAM/HadCM3. Several recent studies find that such high values cannot be excluded based on climatological constraints, but comparison with observations shows the smallest errors for many fields if ECS is between 3 and 4°C (Piani et al., 2005; Knutti et al., 2006; Rodwell and Palmer, 2007; Sanderson et al., 2008a, 2008b, 2010; Sanderson, 2011, 2013).

9.8 Relating Model Performance to Credibility of Model Applications

9.8.1 Synthesis Assessment of Model Performance

This chapter has assessed the performance of individual climate models as well as the multi-model mean. In addition, changes between models available now and those that were available at the time of the AR4 have been documented. The models display a range of abilities to

simulate climate characteristics, underlying processes, and phenomena. No model scores high or low in all performance metrics, but some models perform substantially better than others for specific climate variables or phenomena. For a few climate characteristics, the assessment has shown that some classes of models, for example, those with higher horizontal resolution, higher model top or a more complete representation of the carbon cycle, aerosols or chemistry, agree better with observations, although this is not universally true.

Figure 9.44 provides a synthesis of key model evaluation results for AOGCMs and ESMs. The figure makes use of the calibrated language as defined in Mastrandrea et al. (2011). The *x*-axis refers to the level of confidence which increases towards the right as suggested by the increasing strength of shading. The level of confidence is a combination of the level of evidence and the degree of agreement. The level of evidence includes the number of studies and quality of observational data. Generally, evidence is most robust when there are multiple, independent studies that evaluate multiple models using high-quality observations. The degree of agreement measures whether different studies come to the same conclusions or not. The figure shows that several important aspects of the climate are simulated well by contemporary models, with varying levels of confidence. The colour coding provides an indication of how model quality has changed from CMIP3 to CMIP5. For example, there is *high confidence* that the model performance for global mean surface air temperature (TAS) is high, and it is shown in green because there is *robust evidence* of improvement since CMIP3. By contrast, the diurnal cycle of global mean surface air temperature (TAS-diur) is simulated with medium performance, but there is *low confidence* in this assessment owing to as yet limited analyses. It should be noted that there are no instances in the figure for

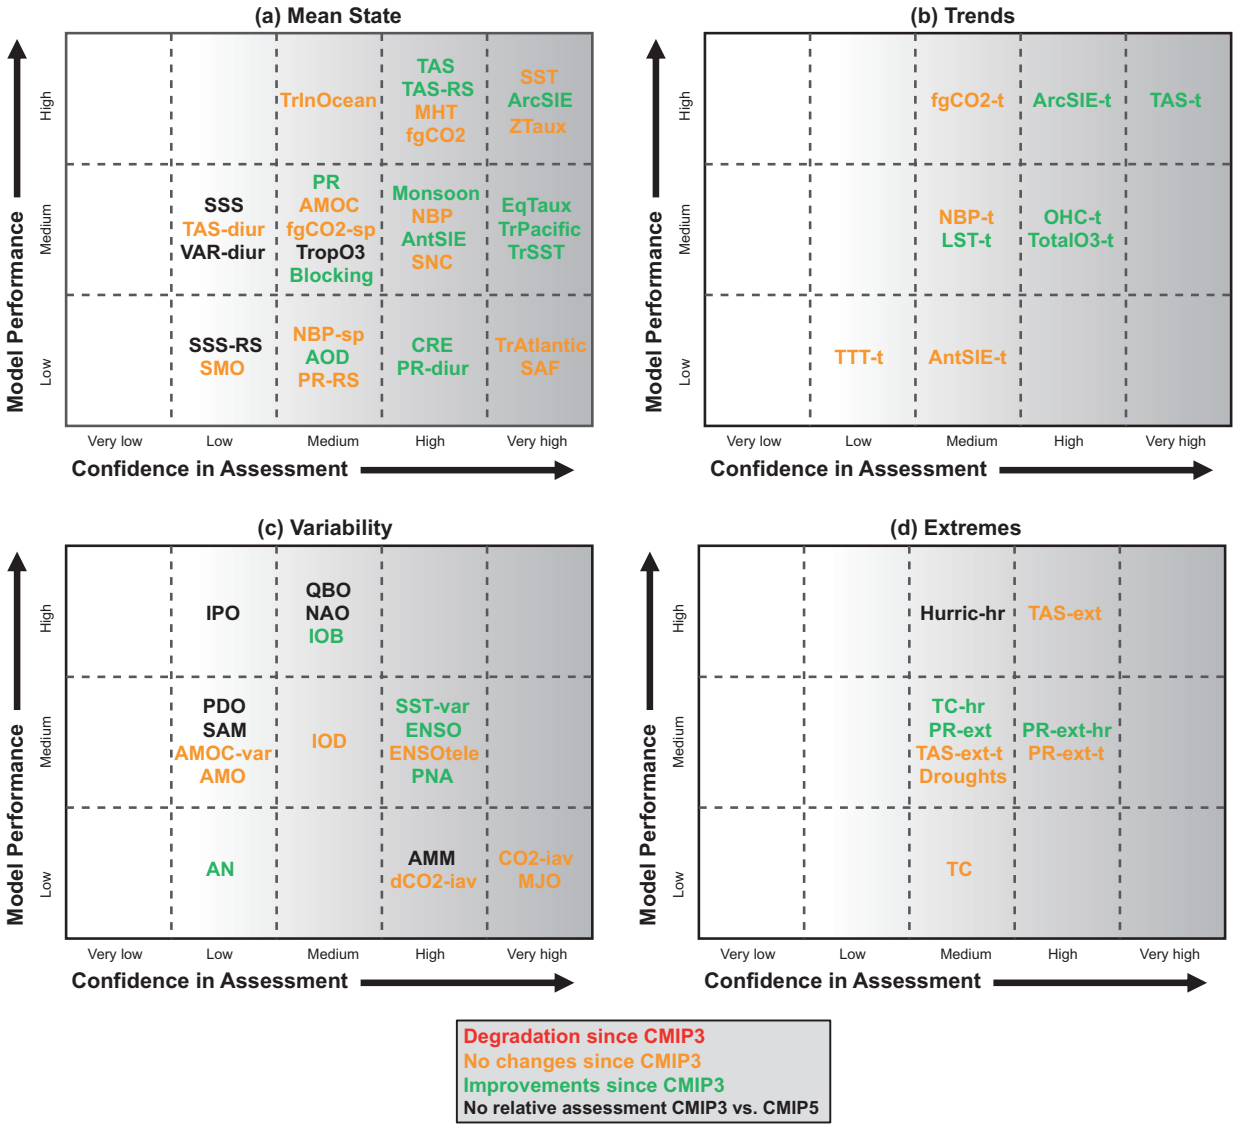

Figure 9.44 | Summary of the findings of Chapter 9 with respect to how well the CMIP5 models simulate important features of the climate of the 20th century. Confidence in the assessment increases towards the right as suggested by the increasing strength of shading. Model performance improves from bottom to top. The colour coding indicates changes since CMIP3 (or models of that generation) to CMIP5. The assessment of model performance is expert judgment based on the agreement with observations of the multi-model mean and distribution of individual models around the mean, taking into account internal climate variability. Note that assessed model performance is simplified for representation in the figure and it is referred to the text for details of each assessment. The figure highlights the following key features, with the sections that back up the assessment added in parentheses:

PANEL a:

AMOC	Atlantic Meridional Overturning Circulation mean (Section 9.4.2.3)
AntSIE	Seasonal cycle Antarctic sea ice extent (Section 9.4.3)
AOD	Aerosol Optical Depth (Section 9.4.6)
ArctSIE	Seasonal cycle Arctic sea ice extent (Section 9.4.3)
Blocking	Blocking events (Section 9.5.2.2)
CRE	Cloud radiative effects (Section 9.4.1.2)
EqTaux	Equatorial zonal wind stress (Section 9.4.2.4)
fgCO2	Global ocean carbon sink (Section 9.4.5)
fgCO2-sp	Spatial pattern of ocean–atmosphere CO_2 fluxes (Section 9.4.5)
MHT	Meridional heat transport (Section 9.4.2.4)
Monsoon	Global monsoon (Section 9.5.2.4)
NBP	Global land carbon sink (Section 9.4.5)
NBP-sp	Spatial pattern of land–atmosphere CO_2 fluxes (Section 9.4.5)
PR	Large scale precipitation (Sections 9.4.1.1, 9.4.1.3)
PR-diur	Diurnal cycle precipitation (Section 9.5.2.1)
PR-RS	Regional scale precipitation (Section 9.6.1.1)
SAF	Snow albedo feedbacks (Section 9.8.3)
SMO	Soil moisture (Section 9.4.4)
SNC	Snow cover (Section 9.4.4)
SSS	Sea surface salinity (Section 9.4.2.1)
SSS-RS	Regional Sea surface salinity (Section 9.4.2.1)
SST	Sea surface temperature (Section 9.4.2.1)
TAS	Large scale surface air temperature (Sections 9.4.1.1, 9.4.1.3)
TAS-diur	Diurnal cycle surface air temperature (Section 9.5.2.1)
TAS-RS	Regional scale surface air temperature (Section 9.6.1.1)
TrSST	Tropical sea surface temperature (Section 9.4.2.1)
TropO3	Tropospheric column ozone climatology (Section 9.4.1.4.5)
TrAtlantic	Tropical Atlantic mean state (Section 9.4.2.5)
TrInOcean	Tropical Indian Ocean mean state (Section 9.4.2.5)
TrPacific	Tropical Pacific mean state (Section 9.4.2.5)
VAR-diur	Diurnal cycle other variables (Section 9.5.2.1)
ZTaux	Zonal mean zonal wind stress (Section 9.4.2.4)

PANEL b (Trends)

AntSIE-t	Trend in Antarctic sea ice extent (Section 9.4.3)
ArctSIE-t	Trend in Arctic sea ice extent (Section 9.4.3)
fgCO2-t	Global ocean carbon sink trends (Section 9.4.5)
LST-t	Lower stratospheric temperature trends (Section 9.4.1.4.5)
NBP-t	Global land carbon sink trends (Section 9.4.5)
OHC-t	Global ocean heat content trends (Section 9.4.2.2)
TotalO3-t	Total column ozone trends (Section 9.4.1.4.5)
TAS-t	Surface air temperature trends (Section 9.4.1.4.1)
TTT-t	Tropical tropospheric temperature trends (Section 9.4.1.4.2)

PANEL c (Variability):

AMM	Atlantic Meridional Mode (Section 9.5.3.3)
AMO	Atlantic Multi-decadal Variability (Section 9.5.3.3)
AMOC-var	Atlantic Meridional Overturning Circulation (Section 9.5.3.3)
AN	Atlantic Niño (Section 9.5.3.3)
CO2-iav	Interannual variability of atmospheric CO_2 (Section 9.8.3)
dCO2-iav	Sensitivity of CO_2 growth rate to tropical temperature (Section 9.8.3)
ENSO	El Niño Southern Oscillation (Section 9.5.3.4)
ENSOtele	Tropical ENSO teleconnections (Section 9.5.3.5)
IOB	Indian Ocean basin mode (Section 9.5.3.4)
IOD	Indian Ocean dipole (Section 9.5.3.4)
IPO	Interdecadal Pacific Oscillation (Section 9.5.3.6)
MJO	Madden-Julian Oscillation (Section 9.5.2.3)
NAO	North Atlantic Oscillation and Northern annular mode (Section 9.5.3.2)
PDO	Pacific Decadal Oscillation (Section 9.5.3.6)
PNA	Pacific North American (Section 9.5.3.5)
QBO	Quasi-Biennial Oscillation (Section 9.5.3.7)
SAM	Southern Annular Mode (Section 9.5.3.2)
SST-var	Global sea surface temperature variability (Section 9.5.3.1)

PANEL d (Extremes):

Hurric-hr	Year-to-year counts of Atlantic hurricanes in high-resolution AGCMs (Section 9.5.4.3)
PR-ext	Global distributions of precipitation extremes (Section 9.5.4.2)
PR-ext-hr	Global distribution of precipitation extremes in high-resolution AGCMs (Section 9.5.4.2)
PR-ext-t	Global trends in precipitation extremes (Section 9.5.4.2)
TAS-ext	Global distributions of surface air temperature extremes (Section 9.5.4.1)
TAS-ext-t	Global trends in surface air temperature extremes (Section 9.5.4.1)
TC	Tropical cyclone tracks and intensity (Section 9.5.4.3)
TC-hr	Tropical cyclone tracks and intensity in high-resolution AGCMs (Section 9.5.4.3)
Droughts	Droughts (Section 9.5.4.4)

which CMIP5 models perform worse than CMIP3 models (something that would have been indicated by the red colour). A description that explains the expert judgment for each of the results presented in Figure 9.44 can be found in the body of this chapter, with a link to the specific sections given in the figure caption.

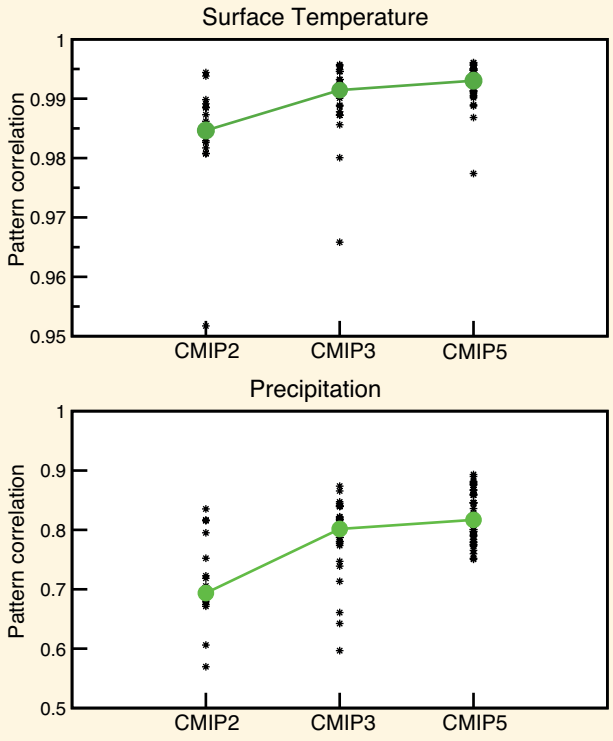
EMICs have also been evaluated to some extent in this chapter as they are used to provide long-term projections (in Chapter 12) beyond year 2300, and to provide large ensembles emulating the response of more comprehensive ESMs and allowing probabilistic estimates. Results from the EMIC intercomparison project (Eby et al., 2013; Zickfeld et al., 2013) illustrate the ability to reproduce the large-scale climate changes in GMST (Figure 9.8) and OHC (Figure 9.17) during the 20th century. The models also estimate CO_2 fluxes for land and oceans, which are as consistent with observations as are fluxes estimated by ESMs (Figure 9.27). This gives confidence that the EMICs, albeit limited in the scope and resolution of information they can provide, can be used for long-term projections compatible with those of ESMs (Plattner et al., 2008; Eby et al., 2013). Overall, these studies imply that EMICs are well suited for simulations extending beyond the CMIP5 ensemble.

Frequently Asked Questions

FAQ 9.1 | Are Climate Models Getting Better, and How Would We Know?

Climate models are extremely sophisticated computer programs that encapsulate our understanding of the climate system and simulate, with as much fidelity as currently feasible, the complex interactions between the atmosphere, ocean, land surface, snow and ice, the global ecosystem and a variety of chemical and biological processes.

The complexity of climate models—the representation of physical processes like clouds, land surface interactions and the representation of the global carbon and sulphur cycles in many models—has increased substantially since the IPCC First Assessment Report in 1990, so in that sense, current Earth System Models are vastly 'better' than the models of that era. This development has continued since the Fourth Assessment, while other factors have also contributed to model improvement. More powerful supercomputers allow current models to resolve finer spatial detail. Today's models also reflect improved understanding of how climate processes work—understanding that has come from ongoing research and analysis, along with new and improved observations.



Climate models of today are, in principle, better than their predecessors. However, every bit of added complexity, while intended to improve some aspect of simulated climate, also introduces new sources of possible error (e.g., via uncertain parameters) and new interactions between model components that may, if only temporarily, degrade a model's simulation of other aspects of the climate system. Furthermore, despite the progress that has been made, scientific uncertainty regarding the details of many processes remains.

An important consideration is that model performance can be evaluated only relative to past observations, taking into account natural internal variability. To have confidence in the future projections of such models, historical climate—and its variability and change—must be well simulated. The scope of model evaluation, in terms of the kind and quantity of observations available, the availability of better coordinated model experiments, and the expanded use of various performance metrics, has provided much more quantitative information about model performance. But this alone may not be sufficient. Whereas weather and seasonal climate predictions can be regularly verified, climate projections spanning a century or more cannot. This is particularly the case as anthropogenic forcing is driving the climate system toward conditions not previously observed in the instrumental record, and it will always be a limitation.

Quantifying model performance is a topic that has featured in all previous IPCC Working Group I Reports. Reading back over these earlier assessments provides a general sense of the improvements that have been made. Past reports have typically provided a rather broad survey of model performance, showing differences between model-calculated versions of various climate quantities and corresponding observational estimates.

Inevitably, some models perform better than others for certain climate variables, but no individual model clearly emerges as 'the best' overall. Recently, there has been progress in computing various performance metrics, which synthesize model performance relative to a range of different observations according to a simple numerical score. Of course, the definition of such a score, how it is computed, the observations used (which have their

(continued on next page)

FAQ 9.1, Figure 1 | Model capability in simulating annual mean temperature and precipitation patterns as illustrated by results of three recent phases of the Coupled Model Intercomparison Project (CMIP2, models from about year 2000; CMIP3, models from about 2005; and CMIP5, the current generation of models). The figure shows the correlation (a measure of pattern similarity) between observed and modelled temperature (upper panel) and precipitation (lower panel). Larger values indicate better correspondence between modelled and observed spatial patterns. The black symbols indicate correlation coefficient for individual models, and the large green symbols indicate the median value (i.e., half of the model results lie above and the other half below this value). Improvement in model performance is evident by the increase in correlation for successive model generations.

FAQ 9.1 (continued)

own uncertainties), and the manner in which various scores are combined are all important, and will affect the end result.

Nevertheless, if the metric is computed consistently, one can compare different generations of models. Results of such comparisons generally show that, although each generation exhibits a range in performance, the average model performance index has improved steadily between each generation. An example of changes in model performance over time is shown in FAQ 9.1, Figure 1, and illustrates the ongoing, albeit modest, improvement. It is interesting to note that both the poorest and best performing models demonstrate improvement, and that this improvement comes in parallel with increasing model complexity and an elimination of artificial adjustments to atmosphere and ocean coupling (so-called 'flux adjustment'). Some of the reasons for this improvement include increased understanding of various climate processes and better representation of these processes in climate models. More comprehensive Earth observations are also driving improvements.

So, yes, climate models are getting better, and we can demonstrate this with quantitative performance metrics based on historical observations. Although future climate projections cannot be directly evaluated, climate models are based, to a large extent, on verifiable physical principles and are able to reproduce many important aspects of past response to external forcing. In this way, they provide a scientifically sound preview of the climate response to different scenarios of anthropogenic forcing.

9.8.2 Implications of Model Evaluation for Climate Change Detection and Attribution

The evaluation of model simulations of historical climate is of direct relevance to detection and attribution (D&A) studies (Chapter 10) since these rely on model-derived patterns (or 'fingerprints') of climate response to external forcing, and on the ability of models to simulate decadal and longer-time scale internal variability (Hegerl and Zwiers, 2011). Conversely, D&A research contributes to model evaluation through estimation of the amplitude of modeled response to various forcings (Section 10.3.1.1.3). The estimated fingerprint for some variables such as water vapor is governed by basic physical processes that are well represented in models and are rather insensitive to model uncertainties (Santer et al., 2009). Figure 9.44 illustrates slight improvements in the representation of some of the modes of variability and climate phenomena discussed in Sections 9.5.2 and 9.5.3, suggesting with *medium confidence* that models now better reproduce internal variability. On the other hand, biases that affect D&A studies remain. An example is the warm bias of lower-stratosphere temperature trends during the satellite period (Section 9.4.1.4.5) that can be linked to uncertainties in stratospheric ozone forcing (Solomon et al., 2012; Santer et al., 2013). Recent studies of climate extremes (Section 9.5.4) also provide evidence that models have reasonable skill in these important attributes of a changing climate; however, there is an indication that models have difficulties in reproducing the right balance between historical changes in cold and warm extremes. They also confirm that resolution affects the confidence that can be placed in the analyses of extreme in precipitation. D&A studies focussed on extreme events are therefore constrained by current model limitations. Lastly, some D&A studies have incorporated model quality results by repeating a multi-model analysis with only the models that agree best with observations (Santer et al., 2009). This model discrimination or weighting is less problematic for D&A analysis than it is for model projections of future climate (Section 9.8.3), because D&A research is focussed on historical and control-run simulations which can be directly evaluated against observations.

9.8.3 Implications of Model Evaluation for Model Projections of Future Climate

Confidence in climate model projections is based on physical understanding of the climate system and its representation in climate models, and on a demonstration of how well models represent a wide range of processes and climate characteristics on various spatial and temporal scales (Knutti et al., 2010b). A climate model's credibility is increased if the model is able to simulate past variations in climate, such as trends over the 20th century and palaeoclimatic changes. Projections from previous IPCC assessments can also be directly compared to observations (see Figures 1.4 and 1.5), with the caveat that these projections were not intended to be predictions over the short time scales for which observations are available to date. Unlike shorter lead forecasts, longer-term climate change projections push models into conditions outside the range observed in the historical period used for evaluation.

In some cases, the spread in climate projections can be reduced by weighting of models according to their ability to reproduce past observed climate. Several studies have explored the use of unequally weighted means, with the weights based on the models' performance in simulating past variations in climate, typically using some performance metric or collection of metrics (Connolley and Bracegirdle, 2007; Murphy et al., 2007; Waugh and Eyring, 2008; Pierce et al., 2009; Reifen and Toumi, 2009; Christensen et al., 2010; Knutti et al., 2010b; Raisanen et al., 2010; Abe et al., 2011; Shiogama et al., 2011; Watterson and Whetton, 2011; Tsushima et al., 2013). When applied to projections of Arctic sea ice, averages in which extra weight is given

to models with the most realistic historical sea ice do give different results than the unweighted mean (Stroeve et al., 2007, 2012; Scherrer, 2011; Massonnet et al., 2012; Wang and Overland, 2012; Overland and Wang, 2013). Another frequently used approach is the re-calibration of model outputs to a given observed value (Boe et al., 2009b; Mahlstein and Knutti, 2012; Wang and Overland, 2012), see further discussion in Section 12.4.6.1. Some studies explicitly formulate a statistical frameworks that relate future observables to climate model output (reviewed in Knutti et al. (2010b) and Stephenson et al. (2012)). Such frameworks not only provide weights for the mean response but also allow the uncertainty in the predicted response to be quantified (Bracegirdle and Stephenson, 2012).

There are several encouraging examples of 'emergent constraints', which are relationships across an ensemble of models between some aspect of Earth System sensitivity and an observable trend or variation in the contemporary climate (Allen and Ingram, 2002; Hall and Qu, 2006; Eyring et al., 2007; Boe et al., 2009a, 2009b; Mahlstein and Knutti, 2010; Son et al., 2010; Huber et al., 2011; Schaller et al., 2011; Bracegirdle and Stephenson, 2012; Fasullo and Trenberth, 2012; O'Gorman, 2012). For example, analyzing the CMIP3 ensemble, Hall and Qu (2006) showed that inter-model variations of snow albedo feedback in the contemporary seasonal cycle strongly correlate with comparably large inter-model variations in this feedback under future climate change. An update of this analysis with CMIP5 models added is shown in Figure 9.45 (left panel). This relationship presumably arises from the fact that surface albedo values in areas covered by snow vary widely across the models, particularly in the heavily vegetated boreal forest zone. Models with higher surface albedos in these areas have a larger contrast between snow-covered and snow-free areas, and hence a stronger snow albedo feedback whether the context is the seasonal variation in sunshine or anthropogenic forcing. Comparison with an observational estimate of snow albedo feedback reveals a large spread with both high and low biases.

The right panel of Figure 9.45 shows another example of an emergent constraint, where the sensitivity of tropical land carbon to warming (i.e., without CO_2 fertilization effects) is related to the sensitivity of the annual CO_2 growth rate to tropical temperature anomalies (Cox et al., 2013)). The horizontal axis is the regression of the atmospheric CO_2 growth rate on the tropical temperature anomaly for each model. The strong statistical relationship between these two variables is consistent with the fact that interannual variability in the CO_2 growth-rate is known to be dominated by the response of tropical land to climatic anomalies, associated particularly with ENSO. Thus the relationship has a physical as well as a statistical basis. The interannual sensitivity of the CO_2 growth rate to tropical temperature can be estimated from observational data. Like the snow albedo feedback example, this inter-model relationship provides a credible means to reduce model spread in the sensitivity of tropical land carbon to tropical climate change.

On the other hand, many studies have failed to find strong relationships between observables and projections. Whetton et al. (2007) and Knutti et al. (2010a) found that correlations between local to regional climatological values and projected changes are small except for a few regions. Scherrer (2011) finds no robust relationship between the ability of the CMIP3 models to represent interannual variability of near-surface air temperature and the amplitude of future warming.Raisanen et al. (2010) report only small (10–20%) reductions in cross-validation error of simulated 21st century temperature changes when weighting the CMIP3 models based on their simulation of the present-day climatology. The main difficulties are sparse coverage in

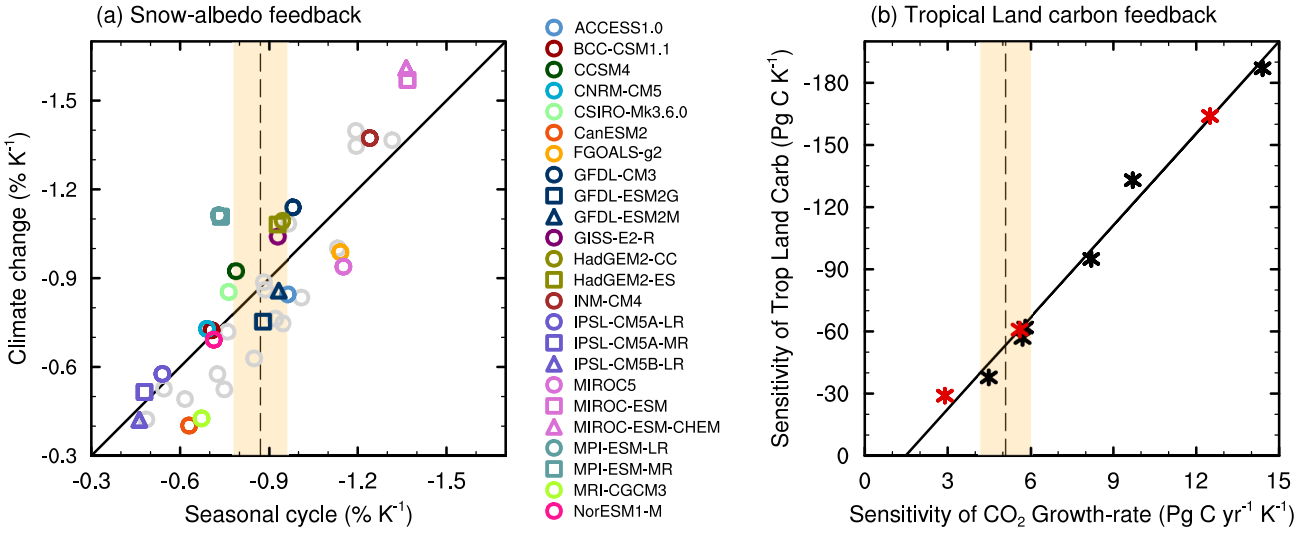


Figure 9.45 | (Left) Scatterplot of simulated springtime snow–albedo feedback ($\Delta\alpha_s/\Delta T_s$) values in climate change (*y*-axis) versus simulated springtime $\Delta\alpha_s/\Delta T_s$ values in the seasonal cycle (*x*-axis) in transient climate change experiments from 17 CMIP3 (blue) and 24 CMIP5 models (α_s and T_s are surface albedo and surface air temperature, respectively). (Adapted from Hall and Qu, 2006.) (Right) Constraint on the climate sensitivity of land carbon in the tropics (30°N to 30°S) from interannual variability in the growth rate of global atmospheric CO_2 (Cox et al., 2013). This is based on results from Earth System Models (ESMs) with free-running CO_2; Coupled Climate Carbon Cycle Model Intercomparison Project General Circulation Models (C4MIP GCMs, black labels; Friedlingstein et al., 2006), and three land carbon 'physics ensembles' with HadCM3 (red labels; Booth et al., 2012b) . The values on the *y*-axis are calculated over the period 1960–2099 inclusive, and those on the *x*-axis over the period 1960–2010 inclusive. In both cases the temperature used is the mean (land+ocean) temperature over 30°N to 30°S. The width of the vertical yellow bands in both (a) and (b) shows the observation-based estimate of the variable on the *x*-axis.

many observed variables, short time series for observed trends, lack of correlation between observed quantities and projected past or future trends, and systematic errors in the models (Tebaldi and Knutti, 2007; Jun et al., 2008; Knutti, 2010; Knutti et al., 2010a), the ambiguity of possible performance metrics and the difficulty of associating them with predictive skill (Parker et al., 2007; Gleckler et al., 2008; Pincus et al., 2008; Reichler and Kim, 2008; Pierce et al., 2009; Knutti et al., 2010a).

Emergent constraints can be difficult to identify if climate models are structurally similar and share common biases, thereby reducing the effective ensemble size. Comparison of emergent constraints in MMEs from different modelling experiments can help reveal which constraints are robust (Massonnet et al., 2012; Bracegirdle and Stephenson, 2013). Another issue is that testing of large numbers of predictors will find statistically significant correlations that do not remain significant in a different ensemble. This is particularly important if many predictors are tested using only small ensembles like CMIP3 (DelSole and Shukla, 2009; Raisanen et al., 2010; Huber et al., 2011; Masson and Knutti, 2013). All of these potential pitfalls underscore the need for analysis of the mechanism underpinning the statistical relationship between current and future climate parameters for any proposed emergent constraint.

Appendix 9.A: Climate Models Assessed in Chapter 9

Table 9.A.1 | Salient features of the Atmosphere–Ocean General Circulation Models (AOGCMs) and Earth System Models (ESMs) participating in CMIP5 (see also Table 9.1). Column 1: Official CMIP5 model name along with the calendar year ('vintage') of the first publication for each model; Column 2: sponsoring institution(s), main reference(s); subsequent columns for each of the model components, with names and main component reference(s). In addition, there are standard entries for the atmosphere component: horizontal grid resolution, number of vertical levels, grid top (low or high top); and for the ocean component: horizontal grid resolution, number of vertical levels, top level, vertical coordinate type, ocean free surface type ('Top BC'). This table information was initially extracted from the CMIP5 online questionnaire (http://q.cmip5.ceda.ac.uk/) as of January 2013. A blank entry indicates that information was not available.

Table 9.A.2 | Salient features of the Earth system Models of Intermediate Complexity (EMICs) assessed in the AR5 (see also Table 9.2). Column 1: Model name used in WG1 and the official model version along with the first publication for each model; subsequent columns for each of the eight component models with specific information and the related references are provided. This information was initially gathered for the EMIC intercomparison project in Eby et al. (2013).

Executive Summary

Atmospheric Temperatures

More than half of the observed increase in global mean surface temperature (GMST) from 1951 to 2010 is *very likely*[1] due to the observed anthropogenic increase in greenhouse gas (GHG) concentrations. The consistency of observed and modeled changes across the climate system, including warming of the atmosphere and ocean, sea level rise, ocean acidification and changes in the water cycle, the cryosphere and climate extremes points to a large-scale warming resulting primarily from anthropogenic increases in GHG concentrations. Solar forcing is the only known natural forcing acting to warm the climate over this period but it has increased much less than GHG forcing, and the observed pattern of long-term tropospheric warming and stratospheric cooling is not consistent with the expected response to solar irradiance variations. The Atlantic Multi-decadal Oscillation (AMO) could be a confounding influence but studies that find a significant role for the AMO show that this does not project strongly onto 1951–2010 temperature trends. {10.3.1, Table 10.1}

It is *extremely likely* that human activities caused more than half of the observed increase in GMST from 1951 to 2010. This assessment is supported by robust evidence from multiple studies using different methods. Observational uncertainty has been explored much more thoroughly than previously and the assessment now considers observations from the first decade of the 21st century and simulations from a new generation of climate models whose ability to simulate historical climate has improved in many respects relative to the previous generation of models considered in AR4. Uncertainties in forcings and in climate models' temperature responses to individual forcings and difficulty in distinguishing the patterns of temperature response due to GHGs and other anthropogenic forcings prevent a more precise quantification of the temperature changes attributable to GHGs. {9.4.1, 9.5.3, 10.3.1, Figure 10.5, Table 10.1}

GHGs contributed a global mean surface warming *likely* to be between 0.5°C and 1.3°C over the period 1951–2010, with the contributions from other anthropogenic forcings *likely* to be between –0.6°C and 0.1°C, from natural forcings *likely* to be between –0.1°C and 0.1°C, and from internal variability *likely* to be between –0.1°C and 0.1°C. Together these assessed contributions are consistent with the observed warming of approximately 0.6°C over this period. {10.3.1, Figure 10.5}

It is *virtually certain* that internal variability alone cannot account for the observed global warming since 1951. The observed global-scale warming since 1951 is large compared to climate model estimates of internal variability on 60-year time scales. The Northern Hemisphere (NH) warming over the same period is far outside the range of any similar length trends in residuals from reconstructions of the past millennium. The spatial pattern of observed warming differs from those associated with internal variability. The model-based simulations of internal variability are assessed to be adequate to make this assessment. {9.5.3, 10.3.1, 10.7.5, Table 10.1}

It is *likely* that anthropogenic forcings, dominated by GHGs, have contributed to the warming of the troposphere since 1961 and *very likely* that anthropogenic forcings, dominated by the depletion of the ozone layer due to ozone-depleting substances, have contributed to the cooling of the lower stratosphere since 1979. Observational uncertainties in estimates of tropospheric temperatures have now been assessed more thoroughly than at the time of AR4. The structure of stratospheric temperature trends and multi-year to decadal variations are well represented by models and physical understanding is consistent with the observed and modelled evolution of stratospheric temperatures. Uncertainties in radiosonde and satellite records make assessment of causes of observed trends in the upper troposphere less confident than an assessment of the overall atmospheric temperature changes. {2.4.4, 9.4.1, 10.3.1, Table 10.1}

Further evidence has accumulated of the detection and attribution of anthropogenic influence on temperature change in different parts of the world. Over every continental region, except Antarctica, it is *likely* that anthropogenic influence has made a substantial contribution to surface temperature increases since the mid-20th century. The robust detection of human influence on continental scales is consistent with the global attribution of widespread warming over land to human influence. It is *likely* that there has been an anthropogenic contribution to the very substantial Arctic warming over the past 50 years. For Antarctica large observational uncertainties result in *low confidence*[2] that anthropogenic influence has contributed to the observed warming averaged over available stations. Anthropogenic influence has *likely* contributed to temperature change in many sub-continental regions. {2.4.1, 10.3.1, Table 10.1}

Robustness of detection and attribution of global-scale warming is subject to models correctly simulating internal variability. Although estimates of multi-decadal internal variability of GMST need to be obtained indirectly from the observational record because the observed record contains the effects of external forcings (meaning the combination of natural and anthropogenic forcings), the standard deviation of internal variability would have to be underestimated in climate models by a factor of at least three to account for the observed warming in the absence of anthropogenic influence. Comparison with observations provides no indication of such a large difference between climate models and observations. {9.5.3, Figures 9.33, 10.2, 10.3.1, Table 10.1}

[1] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0-10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

[2] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

The observed recent warming hiatus, defined as the reduction in GMST trend during 1998–2012 as compared to the trend during 1951–2012, is attributable in roughly equal measure to a cooling contribution from internal variability and a reduced trend in external forcing (expert judgement, *medium confidence*). The forcing trend reduction is primarily due to a negative forcing trend from both volcanic eruptions and the downward phase of the solar cycle. However, there is *low confidence* in quantifying the role of forcing trend in causing the hiatus because of uncertainty in the magnitude of the volcanic forcing trends and *low confidence* in the aerosol forcing trend. Many factors, in addition to GHGs, including changes in tropospheric and stratospheric aerosols, stratospheric water vapour, and solar output, as well as internal modes of variability, contribute to the year-to-year and decade- to-decade variability of GMST. {Box 9.2, 10.3.1, Figure 10.6}

Ocean Temperatures and Sea Level Rise

It is *very likely* that anthropogenic forcings have made a substantial contribution to upper ocean warming (above 700 m) observed since the 1970s. This anthropogenic ocean warming has contributed to global sea level rise over this period through thermal expansion. New understanding since AR4 of measurement errors and their correction in the temperature data sets have increased the agreement in estimates of ocean warming. Observations of ocean warming are consistent with climate model simulations that include anthropogenic and volcanic forcings but are inconsistent with simulations that exclude anthropogenic forcings. Simulations that include both anthropogenic and natural forcings have decadal variability that is consistent with observations. These results are a major advance on AR4. {3.2.3, 10.4.1, Table 10.1}

It is *very likely* that there is a substantial contribution from anthropogenic forcings to the global mean sea level rise since the 1970s. It is *likely* that sea level rise has an anthropogenic contribution from Greenland melt since 1990 and from glacier mass loss since 1960s. Observations since 1971 indicate with *high confidence* that thermal expansion and glaciers (excluding the glaciers in Antarctica) explain 75% of the observed rise. {10.4.1, 10.4.3, 10.5.2, Table 10.1, 13.3.6}

Ocean Acidification and Oxygen Change

It is *very likely* that oceanic uptake of anthropogenic carbon dioxide has resulted in acidification of surface waters which is observed to be between –0.0014 and –0.0024 pH units per year. There is *medium confidence* that the observed global pattern of decrease in oxygen dissolved in the oceans from the 1960s to the 1990s can be attributed in part to human influences. {3.8.2, Box 3.2, 10.4.4, Table 10.1}

The Water Cycle

New evidence is emerging for an anthropogenic influence on global land precipitation changes, on precipitation increases in high northern latitudes, and on increases in atmospheric humidity. There is *medium confidence* that there is an anthropogenic contribution to observed increases in atmospheric specific humidity since 1973 and to global scale changes in precipitation patterns over land since 1950, including increases in NH mid to high latitudes. Remaining observational and modelling uncertainties, and the large internal variability in precipitation, preclude a more confident assessment at this stage. {2.5.1, 2.5.4, 10.3.2, Table 10.1}

It is *very likely* that anthropogenic forcings have made a discernible contribution to surface and subsurface oceanic salinity changes since the 1960s. More than 40 studies of regional and global surface and subsurface salinity show patterns consistent with understanding of anthropogenic changes in the water cycle and ocean circulation. The expected pattern of anthropogenic amplification of climatological salinity patterns derived from climate models is detected in the observations although there remains incomplete understanding of the observed internal variability of the surface and sub-surface salinity fields. {3.3.2, 10.4.2, Table 10.1}

It is *likely* that human influence has affected the global water cycle since 1960. This assessment is based on the combined evidence from the atmosphere and oceans of observed systematic changes that are attributed to human influence in terrestrial precipitation, atmospheric humidity and oceanic surface salinity through its connection to precipitation and evaporation. This is a major advance since AR4. {3.3.2, 10.3.2, 10.4.2, Table 10.1}

Cryosphere

Anthropogenic forcings are *very likely* to have contributed to Arctic sea ice loss since 1979. There is a robust set of results from simulations that show the observed decline in sea ice extent is simulated only when models include anthropogenic forcings. There is *low confidence* in the scientific understanding of the observed increase in Antarctic sea ice extent since 1979 owing to the incomplete and competing scientific explanations for the causes of change and *low confidence* in estimates of internal variability. {10.5.1, Table 10.1}

Ice sheets and glaciers are melting, and anthropogenic influences are *likely* to have contributed to the surface melting of Greenland since 1993 and to the retreat of glaciers since the 1960s. Since 2007, internal variability is *likely* to have further enhanced the melt over Greenland. For glaciers there is a high level of scientific understanding from robust estimates of observed mass loss, internal variability and glacier response to climatic drivers. Owing to a low level of scientific understanding there is *low confidence* in attributing the causes of the observed loss of mass from the Antarctic ice sheet since 1993. {4.3.3, 10.5.2, Table 10.1}

It is *likely* that there has been an anthropogenic component to observed reductions in NH snow cover since 1970. There is high agreement across observations studies and attribution studies find a human influence at both continental and regional scales. {10.5.3, Table 10.1}

Climate Extremes

There has been a strengthening of the evidence for human influence on temperature extremes since the AR4 and IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX) reports. It is *very likely* that anthropogenic forcing has contributed to the observed changes in the frequency and intensity of daily temperature extremes on the global scale since the mid-20th century. Attribution of changes in temperature extremes to anthropogenic influence is robustly seen in independent analyses using different methods and different data sets. It is *likely* that human influence has substantially increased the probability of occurrence of heatwaves in some locations. {10.6.1, 10.6.2, Table 10.1}

In land regions where observational coverage is sufficient for assessment, there is *medium confidence* that anthropogenic forcing has contributed to a global-scale intensification of heavy precipitation over the second half of the 20th century. There is *low confidence* in attributing changes in drought over global land areas since the mid-20th century to human influence owing to observational uncertainties and difficulties in distinguishing decadal-scale variability in drought from long-term trends. {10.6.1, Table 10.1}

There is *low confidence* in attribution of changes in tropical cyclone activity to human influence owing to insufficient observational evidence, lack of physical understanding of the links between anthropogenic drivers of climate and tropical cyclone activity and the low level of agreement between studies as to the relative importance of internal variability, and anthropogenic and natural forcings. This assessment is consistent with that of SREX. {10.6.1, Table 10.1}

Atmospheric Circulation

It is *likely* that human influence has altered sea level pressure patterns globally. Detectable anthropogenic influence on changes in sea level pressure patterns is found in several studies. Changes in atmospheric circulation are important for local climate change since they could lead to greater or smaller changes in climate in a particular region than elsewhere. There is *medium confidence* that stratospheric ozone depletion has contributed to the observed poleward shift of the southern Hadley Cell border during austral summer. There are large uncertainties in the magnitude of this poleward shift. It is *likely* that stratospheric ozone depletion has contributed to the positive trend in the Southern Annular Mode seen in austral summer since the mid-20th century which corresponds to sea level pressure reductions over the high latitudes and an increase in the subtropics. There is *medium confidence* that GHGs have also played a role in these trends of the southern Hadley Cell border and the Southern Annular Mode in Austral summer. {10.3.3, Table 10.1}

A Millennia to Multi-Century Perspective

Taking a longer term perspective shows the substantial role played by anthropogenic and natural forcings in driving climate variability on hemispheric scales prior to the twentieth century. It is *very unlikely* that NH temperature variations from 1400 to 1850 can be explained by internal variability alone. There is *medium confidence* that external forcing contributed to NH temperature variability from 850 to 1400 and that external forcing contributed to European temperature variations over the last five centuries. {10.7.2, 10.7.5, Table 10.1}

Climate System Properties

The extended record of observed climate change has allowed a better characterization of the basic properties of the climate system that have implications for future warming. New evidence from 21st century observations and stronger evidence from a wider range of studies have strengthened the constraint on the transient climate response (TCR) which is estimated with *high confidence* to be *likely* between 1°C and 2.5°C and *extremely unlikely* to be greater than 3°C. The Transient Climate Response to Cumulative CO_2 Emissions (TCRE) is estimated with *high confidence* to be *likely* between 0.8°C and 2.5°C per 1000 PgC for cumulative CO_2 emissions less than about 2000 PgC until the time at which temperatures peak. Estimates of the Equilibrium Climate Sensitivity (ECS) based on multiple and partly independent lines of evidence from observed climate change indicate that there is *high confidence* that ECS is *extremely unlikely* to be less than 1°C and *medium confidence* that the ECS is *likely* to be between 1.5°C and 4.5°C and *very unlikely* greater than 6°C. These assessments are consistent with the overall assessment in Chapter 12, where the inclusion of additional lines of evidence increases confidence in the assessed *likely* range for ECS. {10.8.1, 10.8.2, 10.8.4, Box 12.2}

Combination of Evidence

Human influence has been detected in the major assessed components of the climate system. Taken together, the combined evidence increases the level of confidence in the attribution of observed climate change, and reduces the uncertainties associated with assessment based on a single climate variable. From this combined evidence it is *virtually certain* that human influence has warmed the global climate system. Anthropogenic influence has been identified in changes in temperature near the surface of the Earth, in the atmosphere and in the oceans, as well as changes in the cryosphere, the water cycle and some extremes. There is strong evidence that excludes solar forcing, volcanoes and internal variability as the strongest drivers of warming since 1950. {10.9.2, Table 10.1}

10.1 Introduction

This chapter assesses the causes of observed changes assessed in Chapters 2 to 5 and uses understanding of physical processes, climate models and statistical approaches. The chapter adopts the terminology for detection and attribution proposed by the IPCC good practice guidance paper on detection and attribution (Hegerl et al., 2010) and for uncertainty Mastrandrea et al. (2011). Detection and attribution of impacts of climate changes are assessed by Working Group II, where Chapter 18 assesses the extent to which atmospheric and oceanic changes influence ecosystems, infrastructure, human health and activities in economic sectors.

Evidence of a human influence on climate has grown stronger over the period of the four previous assessment reports of the IPCC. There was little observational evidence for a detectable human influence on climate at the time of the First IPCC Assessment Report. By the time of the second report there was sufficient additional evidence for it to conclude that 'the balance of evidence suggests a discernible human influence on global climate'. The Third Assessment Report found that a distinct greenhouse gas (GHG) signal was robustly detected in the observed temperature record and that 'most of the observed warming over the last fifty years is *likely* to have been due to the increase in greenhouse gas concentrations.'

With the additional evidence available by the time of the Fourth Assessment Report, the conclusions were further strengthened. This evidence included a wider range of observational data, a greater variety of more sophisticated climate models including improved representations of forcings and processes and a wider variety of analysis techniques. This enabled the AR4 report to conclude that 'most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations'. The AR4 also concluded that 'discernible human influences now extend to other aspects of climate, including ocean warming, continental-average temperatures, temperature extremes and wind patterns.'

A number of uncertainties remained at the time of AR4. For example, the observed variability of ocean temperatures appeared inconsistent with climate models, thereby reducing the confidence with which observed ocean warming could be attributed to human influence. Also, although observed changes in global rainfall patterns and increases in heavy precipitation were assessed to be qualitatively consistent with expectations of the response to anthropogenic forcings, detection and attribution studies had not been carried out. Since the AR4, improvements have been made to observational data sets, taking more complete account of systematic biases and inhomogeneities in observational systems, further developing uncertainty estimates, and correcting detected data problems (Chapters 2 and 3). A new set of simulations from a greater number of AOGCMs have been performed as part of the Coupled Model Intercomparison Project Phase 5 (CMIP5). These new simulations have several advantages over the CMIP3 simulations assessed in the AR4 (Hegerl et al., 2007b). They incorporate some moderate increases in resolution, improved parameterizations, and better representation of aerosols (Chapter 9). Importantly for attribution, in which it is necessary to partition the response of the climate system to different forcings, most CMIP5 models include simulations of the response to natural forcings only, and the response to increases in well mixed GHGs only (Taylor et al., 2012).

The advances enabled by this greater wealth of observational and model data are assessed in this chapter. In this assessment, there is increased focus on the extent to which the climate system as a whole is responding in a coherent way across a suite of climate variables such as surface mean temperature, temperature extremes, ocean heat content, ocean salinity and precipitation change. There is also a global to regional perspective, assessing the extent to which not just global mean changes but also spatial patterns of change across the globe can be attributed to anthropogenic and natural forcings.

10.2 Evaluation of Detection and Attribution Methodologies

Detection and attribution methods have been discussed in previous assessment reports (Hegerl et al., 2007b) and the IPCC Good Practice Guidance Paper (Hegerl et al., 2010), to which we refer. This section reiterates key points and discusses new developments and challenges.

10.2.1 The Context of Detection and Attribution

In IPCC Assessments, detection and attribution involve quantifying the evidence for a causal link between external drivers of climate change and observed changes in climatic variables. It provides the central, although not the only (see Section 1.2.3) line of evidence that has supported statements such as 'the balance of evidence suggests a discernible human influence on global climate' or 'most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations.'

The definition of detection and attribution used here follows the terminology in the IPCC guidance paper (Hegerl et al., 2010). '*Detection* of change is defined as the process of demonstrating that climate or a system affected by climate has changed in some defined statistical sense without providing a reason for that change. An identified change is detected in observations if its likelihood of occurrence by chance due to internal variability alone is determined to be small' (Hegerl et al., 2010). *Attribution* is defined as 'the process of evaluating the relative contributions of multiple causal factors to a change or event with an assignment of statistical confidence'. As this wording implies, attribution is more complex than detection, combining statistical analysis with physical understanding (Allen et al., 2006; Hegerl and Zwiers, 2011). In general, a component of an observed change is attributed to a specific causal factor if the observations can be shown to be consistent with results from a process-based model that includes the causal factor in question, and inconsistent with an alternate, otherwise identical, model that excludes this factor. The evaluation of this consistency in both of these cases takes into account internal chaotic variability and known uncertainties in the observations and responses to external causal factors.

Attribution does not require, and nor does it imply, that every aspect of the response to the causal factor in question is simulated correctly. Suppose, for example, the global cooling following a large volcano matches the cooling simulated by a model, but the model underestimates the magnitude of this cooling: the observed global cooling can still be attributed to that volcano, although the error in magnitude would suggest that details of the model response may be unreliable. Physical understanding is required to assess what constitutes a plausible discrepancy above that expected from internal variability. Even with complete consistency between models and data, attribution statements can never be made with 100% certainty because of the presence of internal variability.

This definition of attribution can be extended to include antecedent conditions and internal variability among the multiple causal factors contributing to an observed change or event. Understanding the relative importance of internal versus external factors is important in the analysis of individual weather events (Section 10.6.2), but the primary focus of this chapter will be on attribution to factors external to the climate system, like rising GHG levels, solar variability and volcanic activity.

There are four core elements to any detection and attribution study:

1. Observations of one or more climate variables, such as surface temperature, that are understood, on physical grounds, to be relevant to the process in question

2. An estimate of how external drivers of climate change have evolved before and during the period under investigation, including both the driver whose influence is being investigated (such as rising GHG levels) and potential confounding influences (such as solar activity)

3. A quantitative physically based understanding, normally encapsulated in a model, of how these external drivers are thought to have affected these observed climate variables

4. An estimate, often but not always derived from a physically based model, of the characteristics of variability expected in these observed climate variables due to random, quasi-periodic and chaotic fluctuations generated in the climate system that are not due to externally driven climate change

A climate model driven with external forcing alone is not expected to replicate the observed evolution of internal variability, because of the chaotic nature of the climate system, but it should be able to capture the statistics of this variability (often referred to as 'noise'). The reliability of forecasts of short-term variability is also a useful test of the representation of relevant processes in the models used for attribution, but forecast skill is not necessary for attribution: attribution focuses on changes in the underlying moments of the 'weather attractor', meaning the expected weather and its variability, while prediction focuses on the actual trajectory of the weather around this attractor.

In proposing that 'the process of attribution requires the detection of a change in the observed variable *or closely associated variables*' (Hegerl et al., 2010), the new guidance recognized that it may be possible, in some instances, to attribute a change in a particular variable to some external factor before that change could actually be detected in the variable itself, provided there is a strong body of knowledge that links a change in that variable to some other variable in which a change can be detected and attributed. For example, it is impossible in principle to detect a trend in the frequency of 1-in-100-year events in a 100-year record, yet if the probability of occurrence of these events is physically related to large-scale temperature changes, and we detect and attribute a large-scale warming, then the new guidance allows attribution of a change in probability of occurrence before such a change can be detected in observations of these events alone. This was introduced to draw on the strength of attribution statements from, for example, time-averaged temperatures, to attribute changes in closely related variables.

Attribution of observed changes is not possible without some kind of model of the relationship between external climate drivers and observable variables. We cannot observe a world in which either anthropogenic or natural forcing is absent, so some kind of model is needed to set up and evaluate quantitative hypotheses: to provide estimates of how we would expect such a world to behave and to respond to anthropogenic and natural forcings (Hegerl and Zwiers, 2011). Models may be very simple, just a set of statistical assumptions, or very complex, complete global climate models: it is not necessary, or possible, for them to be correct in all respects, but they must provide a physically consistent representation of processes and scales relevant to the attribution problem in question.

One of the simplest approaches to detection and attribution is to compare observations with model simulations driven with natural forcings alone, and with simulations driven with all relevant natural and anthropogenic forcings. If observed changes are consistent with simulations that include human influence, and inconsistent with those that do not, this would be sufficient for attribution providing there were no other confounding influences and it is assumed that models are simulating the responses to all external forcings correctly. This is a strong assumption, and most attribution studies avoid relying on it. Instead, they typically assume that models simulate the *shape* of the response to external forcings (meaning the large-scale pattern in space and/or time) correctly, but do not assume that models simulate the *magnitude* of the response correctly. This is justified by our fundamental understanding of the origins of errors in climate modelling. Although there is uncertainty in the size of key forcings and the climate response, the overall shape of the response is better known: it is set in time by the timing of emissions and set in space (in the case of surface temperatures) by the geography of the continents and differential responses of land and ocean (see Section 10.3.1.1.2).

So-called 'fingerprint' detection and attribution studies characterize their results in terms of a best estimate and uncertainty range for 'scaling factors' by which the model-simulated responses to individual forcings can be scaled up or scaled down while still remaining consistent with the observations, accounting for similarities between the patterns of response to different forcings and uncertainty due to internal climate variability. If a scaling factor is significantly larger than zero (at some significance level), then the response to that forcing, as simulated by

that model and given that estimate of internal variability and other potentially confounding responses, is detectable in these observations, whereas if the scaling factor is consistent with unity, then that model-simulated response is consistent with observed changes. Studies do not require scaling factors to be consistent with unity for attribution, but any discrepancy from unity should be understandable in terms of known uncertainties in forcing or response: a scaling factor of 10, for example, might suggest the presence of a confounding factor, calling into question any attribution claim. Scaling factors are estimated by fitting model-simulated responses to observations, so results are unaffected, at least to first order, if the model has a transient climate response, or aerosol forcing, that is too low or high. Conversely, if the spatial or temporal *pattern* of forcing or response is wrong, results can be affected: see Box 10.1 and further discussion in Section 10.3.1.1 and Hegerl and Zwiers (2011) and Hegerl et al. (2011b). Sensitivity of results to the pattern of forcing or response can be assessed by comparing results across multiple models or by representing pattern uncertainty explicitly (Huntingford et al., 2006), but errors that are common to all models (through limited vertical resolution, for example) will not be addressed in this way and are accounted for in this assessment by downgrading overall assessed likelihoods to be generally more conservative than the quantitative likelihoods provided by individual studies.

Attribution studies must compromise between estimating responses to different forcings separately, which allows for the possibility of different errors affecting different responses (errors in aerosol forcing that do not affect the response to GHGs, for example), and estimating responses to combined forcings, which typically gives smaller uncertainties because it avoids the issue of 'degeneracy': if two responses have very similar shapes in space and time, then it may be impossible to estimate the magnitude of both from a single set of observations because amplification of one may be almost exactly compensated for by amplification or diminution of the other (Allen et al., 2006). Many studies find it is possible to estimate the magnitude of the responses to GHG and other anthropogenic forcings separately, particularly when spatial information is included. This is important, because it means the estimated response to GHG increase is not dependent on the uncertain magnitude of forcing and response due to aerosols (Hegerl et al., 2011b).

The simplest way of fitting model-simulated responses to observations is to assume that the responses to different forcings add linearly, so the response to any one forcing can be scaled up or down without affecting any of the others and that internal climate variability is independent of the response to external forcing. Under these conditions, attribution can be expressed as a variant of linear regression (see Box 10.1). The additivity assumption has been tested and found to hold for large-scale temperature changes (Meehl et al., 2003; Gillett et al., 2004) but it might not hold for other variables like precipitation (Hegerl et al., 2007b; Hegerl and Zwiers, 2011; Shiogama et al., 2012), nor for regional temperature changes (Terray, 2012). In principle, additivity is not required for detection and attribution, but to date non-additive approaches have not been widely adopted.

The estimated properties of internal climate variability play a central role in this assessment. These are either estimated empirically from the observations (Section 10.2.2) or from paleoclimate reconstructions (Section 10.7.1) (Esper et al., 2012) or derived from control simulations of coupled models (Section 10.2.3). The majority of studies use modelled variability and routinely check that the residual variability from observations is consistent with modelled internal variability used over time scales shorter than the length of the instrumental record (Allen and Tett, 1999). Assessing the accuracy of model-simulated variability on longer time scales using paleoclimate reconstructions is complicated by the fact that some reconstructions may not capture the full spectrum of variability because of limitations of proxies and reconstruction methods, and by the unknown role of external forcing in the pre-instrumental record. In general, however, paleoclimate reconstructions provide no clear evidence either way whether models are over- or underestimating internal variability on time scales relevant for attribution (Esper et al., 2012; Schurer et al., 2013).

10.2.2 Time Series Methods, Causality and Separating Signal from Noise

Some studies attempt to distinguish between externally driven climate change and changes due to internal variability minimizing the use of climate models, for example, by separating signal and noise by time scale (Schneider and Held, 2001), spatial pattern (Thompson et al., 2009) or both. Other studies use model control simulations to identify patterns of maximum predictability and contrast these with the forced component in climate model simulations (DelSole et al., 2011): see Section 10.3.1. Conclusions of most studies are consistent with those based on fingerprint detection and attribution, while using a different set of assumptions (see review in Hegerl and Zwiers, 2011).

A number of studies have applied methods developed in the econometrics literature (Engle and Granger, 1987) to assess the evidence for a causal link between external drivers of climate and observed climate change, using the observations themselves to estimate the expected properties of internal climate variability (e.g., Kaufmann and Stern, 1997). The advantage of these approaches is that they do not depend on the accuracy of any complex global climate model, but they nevertheless have to assume some kind of model, or restricted class of models, of the properties of the variables under investigation. Attribution is impossible without a model: although this model may be implicit in the statistical framework used, it is important to assess its physical consistency (Kaufmann et al., 2013). Many of these time series methods can be cast in the overall framework of co-integration and error correction (Kaufmann et al., 2011), which is an approach to analysing relationships between stationary and non-stationary time series. If there is a consistent causal relationship between two or more possibly non-stationary time series, then it should be possible to find a linear combination such that the residual is stationary (contains no stochastic trend) over time (Kaufmann and Stern, 2002; Kaufmann et al., 2006; Mills, 2009). Co-integration methods are thus similar in overall principle to regression-based approaches (e.g., Douglass et al., 2004; Stone and Allen, 2005; Lean, 2006) to the extent that regression studies take into account the expected time series properties of the data—the example described in Box 10.1 might be characterized as looking for a linear combination of anthropogenic and natural forcings such that the observed residuals were consistent with internal climate variability as simulated by the CMIP5 models. Co-integration and error correction methods, however, generally make more explicit use of time

Box 10.1 | How Attribution Studies Work

This box presents an idealized demonstration of the concepts underlying most current approaches to detection and attribution of climate change and how these relate to conventional linear regression. The coloured dots in Box 10.1a, Figure 1 show observed annual GMST from 1861 to 2012, with warmer years coloured red and colder years coloured blue. Observations alone indicate, unequivocally, that the Earth has warmed, but to quantify how different external factors have contributed to this warming, studies must compare such observations with the expected responses to these external factors. The orange line shows an estimate of the GMST response to anthropogenic (GHG and aerosol) forcing obtained from the mean of the CMIP3 and CMIP5 ensembles, while the blue line shows the CMIP3/CMIP5 ensemble mean response to natural (solar and volcanic) forcing.

In statistical terms, attribution involves finding the combination of these anthropogenic and natural responses that best fits these observations: this is shown by the black line in panel (a). To show how this fit is obtained in non-technical terms, the data are plotted against model-simulated anthropogenic warming, instead of time, in panel (b). There is a strong correlation between observed temperatures and model-simulated anthropogenic warming, but because of the presence of natural factors and internal climate variability, correlation alone is not enough for attribution.

To quantify how much of the observed warming is attributable to human influence, panel (c) shows observed temperatures plotted against the model-simulated response to anthropogenic forcings in one direction and natural forcings in the other. Observed temperatures increase with both natural and anthropogenic model-simulated warming: the warmest years are in the far corner of the box. A flat surface through these points (here obtained by an ordinary least-squares fit), indicated by the coloured mesh, slopes up away from the viewer.

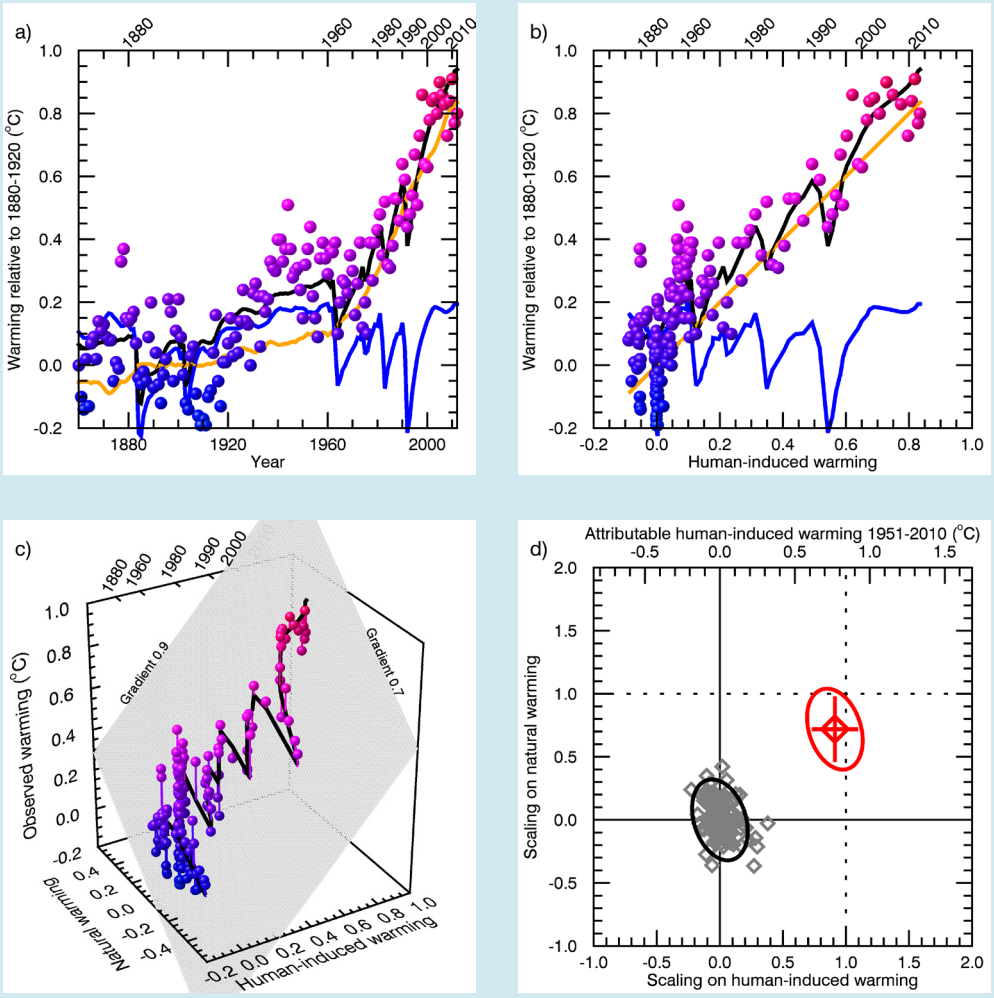
The orientation of this surface indicates how model-simulated responses to natural and anthropogenic forcing need to be scaled to reproduce the observations. The best-fit gradient in the direction of anthropogenic warming (visible on the rear left face of the box) is 0.9, indicating the CMIP3/CMIP5 ensemble average overestimates the magnitude of the observed response to anthropogenic forcing by about 10%. The best-fit gradient in the direction of natural changes (visible on the rear right face) is 0.7, indicating that the observed response to natural forcing is 70% of the average model-simulated response. The black line shows the points on this flat surface that are directly above or below the observations: each 'pin' corresponds to a different year. When re-plotted against time, indicated by the years on the rear left face of the box, this black line gives the black line previously seen in panel (a). The length of the pins indicates 'residual' temperature fluctuations due to internal variability.

The timing of these residual temperature fluctuations is unpredictable, representing an inescapable source of uncertainty. We can quantify this uncertainty by asking how the gradients of the best-fit surface might vary if El Niño events, for example, had occurred in different years in the observed temperature record. To do this, we repeat the analysis in panel (c), replacing observed temperatures with samples of simulated internal climate variability from control runs of coupled climate models. Grey diamonds in panel (d) show the results: these gradients cluster around zero, because control runs have no anthropogenic or natural forcing, but there is still some scatter. Assuming that internal variability in global temperature simply adds to the response to external forcing, this scatter provides an estimate of uncertainty in the gradients, or scaling factors, required to reproduce the observations, shown by the red cross and ellipse.

The red cross and ellipse are clearly separated from the origin, which means that the slope of the best-fit surface through the observations cannot be accounted for by internal variability: some climate change is detected in these observations. Moreover, it is also separated from both the vertical and horizontal axes, which means that the responses to both anthropogenic and natural factors are individually detectable.

The magnitude of observed temperature change is consistent with the CMIP3/CMIP5 ensemble average response to anthropogenic forcing (uncertainty in this scaling factor spans unity) but is significantly lower than the model-average response to natural forcing (this 5 to 95% confidence interval excludes unity). There are, however, reasons why these models may be underestimating the response to volcanic forcing (e.g., Driscoll et al, 2012), so this discrepancy does not preclude detection and attribution of both anthropogenic and natural influence, as simulated by the CMIP3/CMIP5 ensemble average, in the observed GMST record.

The top axis in panel (d) indicates the attributable anthropogenic warming over 1951–2010, estimated from the anthropogenic warming in the CMIP3/CMIP5 ensemble average, or the gradient of the orange line in panel (a) over this period. Because the model-simulated responses have been scaled to fit the observations, the attributable anthropogenic warming in this example is 0.6°C to 0.9°C and does not depend on the magnitude of the raw model-simulated changes. Hence an attribution statement based on such an analysis,



(continued on next page)

Box 10.1 (continued)

such as 'most of the warming over the past 50 years is attributable to anthropogenic drivers', depends only on the shape, or time history, not the size, of the model-simulated warming, and hence does not depend on the models' sensitivity to rising GHG levels.

Formal attribution studies like this example provide objective estimates of how much recent warming is attributable to human influence. Attribution is not, however, a purely statistical exercise. It also requires an assessment that there are no confounding factors that could have caused a large part of the 'attributed' change. Statistical tests can be used to check that observed residual temperature fluctuations (the lengths and clustering of the pins in panel (c)) are consistent with internal variability expected from coupled models, but ultimately these tests must complement physical arguments that the combination of responses to anthropogenic and natural forcing is the only available consistent explanation of recent observed temperature change.

This demonstration assumes, for visualization purposes, that there are only two candidate contributors to the observed warming, anthropogenic and natural, and that only GMST is available. More complex attribution problems can be undertaken using the same principles, such as aiming to separate the response to GHGs from other anthropogenic factors by also including spatial information. These require, in effect, an extension of panel (c), with additional dimensions corresponding to additional causal factors, and additional points corresponding to temperatures in different regions.

Box 10.1, Figure 1 | Example of a simplified detection and attribution study. (a) Observed global annual mean temperatures relative to 1880–1920 (coloured dots) compared with CMIP3/CMIP5 ensemble-mean response to anthropogenic forcing (orange), natural forcing (blue) and best-fit linear combination (black). (b) As (a) but all data plotted against model-simulated anthropogenic warming in place of time. Selected years (increasing nonlinearly) shown on top axis. (c) Observed temperatures versus model-simulated anthropogenic and natural temperature changes, with best-fit plane shown by coloured mesh. (d) Gradient of best-fit plane in (c), or scaling on model-simulated responses required to fit observations (red diamond) with uncertainty estimate (red ellipse and cross) based on CMIP5 control integrations (grey diamonds). Implied attributable anthropogenic warming over the period 1951–2010 is indicated by the top axis. Anthropogenic and natural responses are noise-reduced with 5-point running means, with no smoothing over years with major volcanoes.

series properties (notice how date information is effectively discarded in panel (b) of Box 10.1, Figure 1) and require fewer assumptions about the stationarity of the input series.

All of these approaches are subject to the issue of confounding factors identified by Hegerl and Zwiers (2011). For example, Beenstock et al. (2012) fail to find a consistent co-integrating relationship between atmospheric carbon dioxide (CO_2) concentrations and GMST using polynomial cointegration tests, but the fact that CO_2 concentrations are derived from different sources in different periods (ice cores prior to the mid-20th-century, atmospheric observations thereafter) makes it difficult to assess the physical significance of their result, particularly in the light of evidence for co-integration between temperature and radiative forcing (RF) reported by Kaufmann et al. (2011) using tests of linear cointegration, and also the results of Gay-Garcia et al. (2009), who find evidence for external forcing of climate using time series properties.

The assumptions of the statistical model employed can also influence results. For example, Schlesinger and Ramankutty (1994) and Zhou and Tung (2013a) show that GMST are consistent with a linear anthropogenic trend, enhanced variability due to an approximately 70-year Atlantic Meridional Oscillation (AMO) and shorter-term variability. If, however, there are physical grounds to expect a nonlinear anthropogenic trend (see Box 10.1 Figure 1a), the assumption of a linear trend can itself enhance the variance assigned to a low-frequency oscillation. The fact that the AMO index is estimated from detrended historical temperature observations further increases the risk that its variance may be overestimated, because regressors and regressands are not independent. Folland et al. (2013), using a physically based estimate of the anthropogenic trend, find a smaller role for the AMO in recent warming.

Time series methods ultimately depend on the structural adequacy of the statistical model employed. Many such studies, for example, use models that assume a single exponential decay time for the response to both external forcing and stochastic fluctuations. This can lead to an overemphasis on short-term fluctuations, and is not consistent with the response of more complex models (Knutti et al., 2008). Smirnov and Mokhov (2009) propose an alternative characterization that allows them to distinguish a 'long-term causality' that focuses on low-frequency changes. Trends that appear significant when tested against an AR(1) model may not be significant when tested against a process that supports this 'long-range dependence' (Franzke, 2010). Although the evidence for long-range dependence in global temperature data remains a topic of debate (Mann, 2011; Rea et al., 2011) , it is generally desirable to explore sensitivity of results to the specification of the statistical model, and also to other methods of estimating the properties of internal variability, such as more complex climate models, discussed next. For example, Imbers et al. (2013) demonstrate that the detection of the influence of increasing GHGs in the global temperature record is robust to the assumption of a Fractional Differencing (FD) model of internal variability, which supports long-range dependence.

10.2.3 Methods Based on General Circulation Models and Optimal Fingerprinting

Fingerprinting methods use climate model simulations to provide more complete information about the expected response to different external drivers, including spatial information, and the properties of internal climate variability. This can help to separate patterns of forced change both from each other and from internal variability. The price, however, is that results depend to some degree on the accuracy of the shape of model-simulated responses to external factors (e.g., North and Stevens, 1998), which is assessed by comparing results obtained with expected responses estimated from different climate models. When the signal-to-noise (S/N) ratio is low, as can be the case for some regional indicators and some variables other than temperature, the accuracy of the specification of variability becomes a central factor in the reliability of any detection and attribution study. Many studies of such variables inflate the variability estimate from models to determine if results are sensitive to, for example, doubling of variance in the control (e.g., Zhang et al., 2007), although Imbers et al. (2013) note that errors in the spectral properties of simulated variability may also be important.

A full description of optimal fingerprinting is provided in Appendix 9.A of Hegerl et al. (2007b) and further discussion is to be found in Hasselmann (1997), Allen and Tett (1999), Allen et al. (2006), and Hegerl and Zwiers (2011). Box 10.1 provides a simple example of 'fingerprinting' based on GMST alone. In a typical fingerprint analysis, model-simulated spatio-temporal patterns of response to different combinations of external forcings, including segments of control integrations with no forcing, are 'observed' in a similar manner to the historical record (masking out times and regions where observations are absent). The magnitudes of the model-simulated responses are then estimated in the observations using a variant of linear regression, possibly allowing for signals being contaminated by internal variability (Allen and Stott, 2003) and structural model uncertainty (Huntingford et al., 2006).

In 'optimal' fingerprinting, model-simulated responses and observations are normalized by internal variability to improve the S/N ratio. This requires an estimate of the inverse noise covariance estimated from the sample covariance matrix of a set of unforced (control) simulations (Hasselmann, 1997), or from variations within an initial-condition ensemble. Because these control runs are generally too short to estimate the full covariance matrix, a truncated version is used, retaining only a small number, typically of order 10 to 20, of high-variance principal components. Sensitivity analyses are essential to ensure results are robust to this, relatively arbitrary, choice of truncation (Allen and Tett, 1999; Ribes and Terray, 2013; Jones et al., 2013). Ribes et al. (2009) use a regularized estimate of the covariance matrix, meaning a linear combination of the sample covariance matrix and a unit matrix that has been shown (Ledoit and Wolf, 2004) to provide a more accurate estimate of the true covariance, thereby avoiding dependence on truncation. Optimization of S/N ratio is not, however, essential for many attribution results (see, e.g., Box 10.1) and uncertainty analysis in conventional optimal fingerprinting does not require the covariance matrix to be inverted, so although regularization may help in some cases, it is not essential. Ribes et al. (2010) also propose a hybrid of the model-based optimal fingerprinting and time series approaches, referred to as 'temporal optimal detection', under which each signal is assumed to consist of a single spatial pattern modulated by a smoothly varying time series estimated from a climate model (see also Santer et al., 1994).

The final statistical step in an attribution study is to check that the residual variability, after the responses to external drivers have been estimated and removed, is consistent with the expected properties of internal climate variability, to ensure that the variability used for uncertainty analysis is realistic, and that there is no evidence that a potentially confounding factor has been omitted. Many studies use a standard *F*-test of residual consistency for this purpose (Allen and Tett, 1999). Ribes et al. (2013) raise some issues with this test, but key results are not found to be sensitive to different formulations. A more important issue is that the *F*-test is relatively weak (Berliner et al., 2000; Allen et al., 2006; Terray, 2012), so 'passing' this test is not a safeguard against unrealistic variability, which is why estimates of internal variability are discussed in detail in this chapter and in Chapter 9.

A further consistency check often used in optimal fingerprinting is whether the estimated magnitude of the externally driven responses are consistent between model and observations (scaling factors consistent with unity in Box 10.1): if they are not, attribution is still possible provided the discrepancy is explicable in terms of known uncertainties in the magnitude of either forcing or response. As is emphasized in Section 10.2.1 and Box 10.1, attribution is not a purely statistical assessment: physical judgment is required to assess whether the combination of responses considered allows for all major potential confounding factors and whether any remaining discrepancies are consistent with a physically based understanding of the responses to external forcing and internal climate variability.

10.2.4 Single-Step and Multi-Step Attribution and the Role of the Null Hypothesis

Attribution studies have traditionally involved explicit simulation of the response to external forcing of an observable variable, such as surface temperature, and comparison with corresponding observations of that variable. This so-called 'single-step attribution' has the advantage of simplicity, but restricts attention to variables for which long and consistent time series of observations are available and that can be simulated explicitly in current models driven solely with external climate forcing.

To address attribution questions for variables for which these conditions are not satisfied, Hegerl et al. (2010) introduced the notation of 'multi-step attribution', formalizing existing practice (e.g., Stott et al., 2004). In a multi-step attribution study, the attributable change in a variable such as large-scale surface temperature is estimated with a single-step procedure, along with its associated uncertainty, and the implications of this change are then explored in a further (physically or statistically based) modelling step. Overall conclusions can only be as robust as the least certain link in the multi-step procedure. As the focus shifts towards more noisy regional changes, it can be difficult to separate the effect of different external forcings. In such cases, it can be useful to detect the response to all external forcings, and then determine the most important factors underlying the attribution results by reference to a closely related variable for which a full attribution analysis is available (e.g., Morak et al., 2011).

Attribution results are typically expressed in terms of conventional 'frequentist' confidence intervals or results of hypothesis tests: when it is reported that the response to anthropogenic GHG increase is *very likely* greater than half the total observed warming, it means that the null hypothesis that the GHG-induced warming is less than half the total can be rejected with the data available at the 10% significance level. Expert judgment is required in frequentist attribution assessments, but its role is limited to the assessment of whether internal variability and potential confounding factors have been adequately accounted for, and to downgrade nominal significance levels to account for remaining uncertainties. Uncertainties may, in some cases, be further reduced if prior expectations regarding attribution results themselves are incorporated, using a Bayesian approach, but this not currently the usual practice.

This traditional emphasis on single-step studies and placing lower bounds on the magnitude of signals under investigation means that, very often, the communication of attribution results tends to be conservative, with attention focussing on whether or not human influence in a particular variable might be zero, rather than the upper end of the confidence interval, which might suggest a possible response much bigger than current model-simulated changes. Consistent with previous Assessments and the majority of the literature, this chapter adopts this conservative emphasis. It should, however, be borne in mind that this means that positive attribution results will tend to be biased towards well-observed, well-modelled variables and regions, which should be taken into account in the compilation of global impact assessments (Allen, 2011; Trenberth, 2011a).

10.3 Atmosphere and Surface

This section assesses causes of change in the atmosphere and at the surface over land and ocean.

10.3.1 Temperature

Temperature is first assessed near the surface of the Earth in Section 10.3.1.1 and then in the free atmosphere in Section 10.3.1.2.

10.3.1.1 Surface (Air Temperature and Sea Surface Temperature)

10.3.1.1.1 Observations of surface temperature change

GMST warmed strongly over the period 1900–1940, followed by a period with little trend, and strong warming since the mid-1970s (Section 2.4.3, Figure 10.1). Almost all observed locations have warmed since 1901 whereas over the satellite period since 1979 most regions have warmed while a few regions have cooled (Section 2.4.3; Figure 10.2). Although this picture is supported by all available global near-surface temperature data sets, there are some differences in detail between them, but these are much smaller than both interannual variability and the long-term trend (Section 2.4.3). Since 1998 the trend in GMST has been small (see Section 2.4.3, Box 9.2). Urbanization is *unlikely* to have caused more than 10% of the measured centennial trend in land mean surface temperature, though it may have contributed substantially more to regional mean surface temperature trends in rapidly developing regions (Section 2.4.1.3).

10.3.1.1.2 Simulations of surface temperature change

As discussed in Section 10.1, the CMIP5 simulations have several advantages compared to the CMIP3 simulations assessed by (Hegerl et al., 2007b) for the detection and attribution of climate change. Figure 10.1a shows that when the effects of anthropogenic and natural external forcings are included in the CMIP5 simulations the spread of simulated GMST anomalies spans the observational estimates of GMST anomaly in almost every year whereas this is not the case for simulations in which only natural forcings are included (Figure 10.1b) (see also Jones et al., 2013; Knutson et al., 2013). Anomalies are shown relative to 1880–1919 rather than absolute temperatures. Showing anomalies is necessary to prevent changes in observational coverage being reflected in the calculated global mean and is reasonable

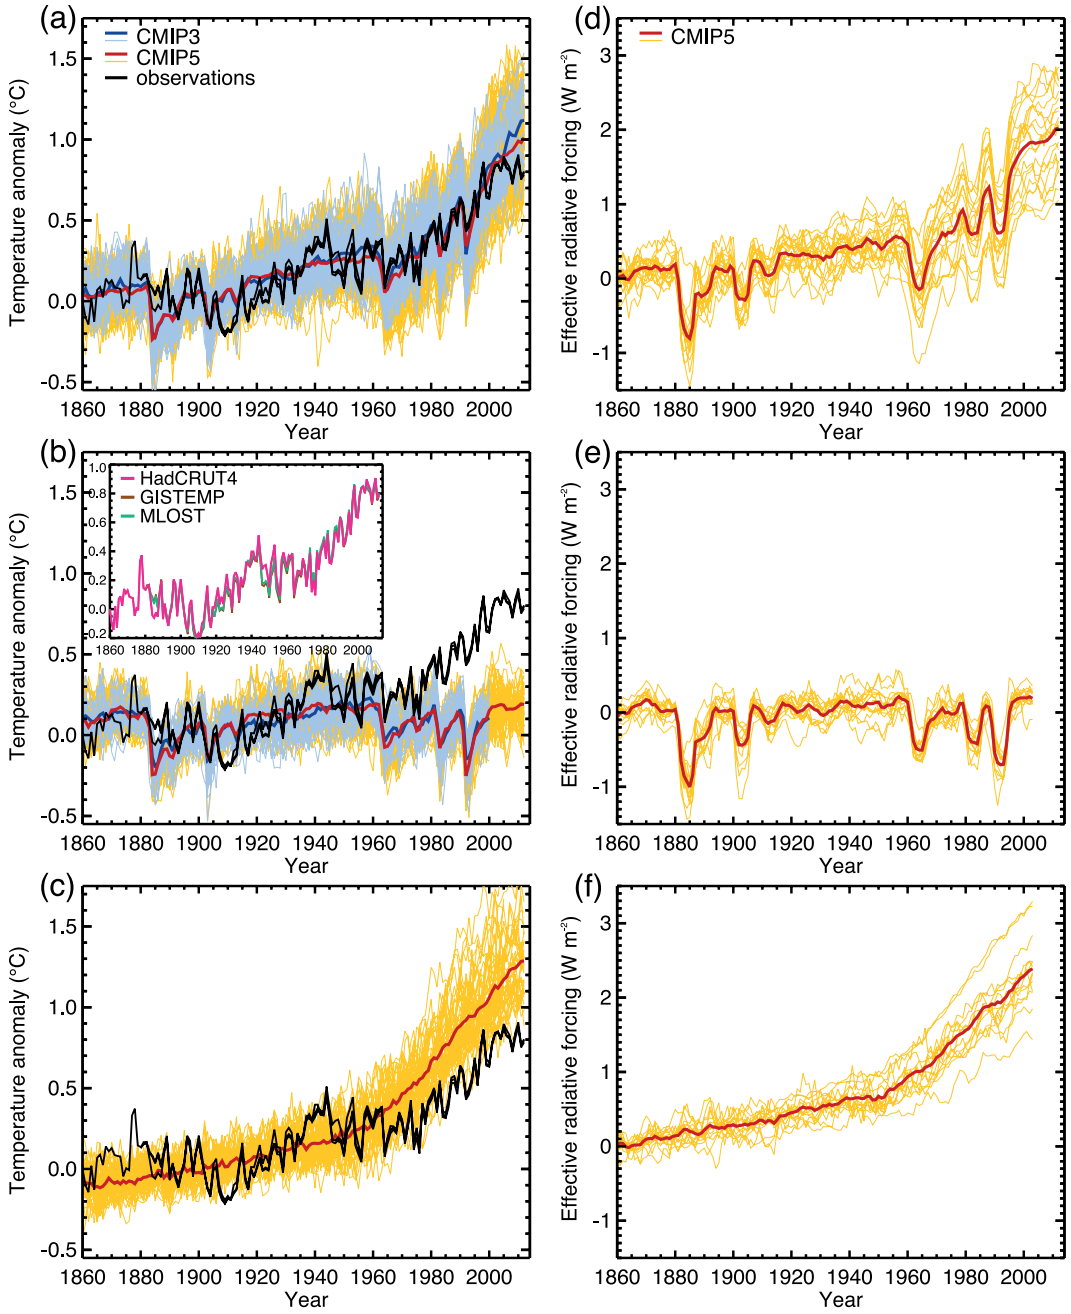


Figure 10.1 | (Left-hand column) Three observational estimates of global mean surface temperature (GMST, black lines) from Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4), Goddard Institute of Space Studies Surface Temperature Analysis (GISTEMP), and Merged Land–Ocean Surface Temperature Analysis (MLOST), compared to model simulations [CMIP3 models – thin blue lines and CMIP5 models – thin yellow lines] with anthropogenic and natural forcings (a), natural forcings only (b) and greenhouse gas (GHG) forcing only (c). Thick red and blue lines are averages across all available CMIP5 and CMIP3 simulations respectively. CMIP3 simulations were not available for GHG forcing only (c). All simulated and observed data were masked using the HadCRUT4 coverage (as this data set has the most restricted spatial coverage), and global average anomalies are shown with respect to 1880–1919, where all data are first calculated as anomalies relative to 1961–1990 in each grid box. Inset to (b) shows the three observational data sets distinguished by different colours. (Adapted from Jones et al., 2013.) (Right-hand column) Net adjusted forcing in CMIP5 models due to anthropogenic and natural forcings (d), natural forcings only (e) and GHGs only (f). (From Forster et al., 2013.) Individual ensemble members are shown by thin yellow lines, and CMIP5 multi-model means are shown as thick red lines.

because climate sensitivity is not a strong function of the bias in GMST in the CMIP5 models (Section 9.7.1; Figure 9.42). Simulations with GHG changes only, and no changes in aerosols or other forcings, tend to simulate more warming than observed (Figure 10.1c), as expected. Better agreement between models and observations when the models include anthropogenic forcings is also seen in the CMIP3 simulations (Figure 10.1, thin blue lines). RF in the simulations including anthropogenic and natural forcings differs considerably among models (Figure 10.1d), and forcing differences explain much of the differences in temperature response between models over the historical period (Forster et al., 2013). Differences between observed GMST based on three observational data sets are small compared to forced changes (Figure 10.1).

As discussed in Section 10.2, detection and attribution assessments are more robust if they consider more than simple consistency arguments. Analyses that allow for the possibility that models might be consistently over- or underestimating the magnitude of the response to climate forcings are assessed in Section 10.3.1.1.3, the conclusions from which are not affected by evidence that model spread in GMST in CMIP3, is smaller than implied by the uncertainty in RF (Schwartz et al., 2007). Although there is evidence that CMIP3 models with a higher climate sensitivity tend to have a smaller increase in RF over the historical period (Kiehl, 2007; Knutti, 2008; Huybers, 2010), no such relationship was found in CMIP5 (Forster et al., 2013) which may explain the wider spread of the CMIP5 ensemble compared to the CMIP3 ensemble (Figure 10.1a). Climate model parameters are typically chosen primarily to reproduce features of the mean climate and variability (Box 9.1), and CMIP5 aerosol emissions are standardized across models and based on historical emissions (Lamarque et al., 2010; Section 8.2.2), rather than being chosen by each modelling group independently (Curry and Webster, 2011; Hegerl et al., 2011c).

Figure 10.2a shows the pattern of annual mean surface temperature trends observed over the period 1901–2010, based on Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4). Warming has been observed at almost all locations with sufficient observations available since 1901. Rates of warming are generally higher over land areas compared to oceans, as is also apparent over the 1951–2010 period (Figure 10.2c), which simulations indicate is due mainly to differences in local feedbacks and a net anomalous heat transport from oceans to land under GHG forcing, rather than differences in thermal inertia (e.g., Boer, 2011). Figure 10.2e demonstrates that a similar pattern of warming is simulated in the CMIP5 simulations with natural and anthropogenic forcing over the 1901–2010 period. Over most regions, observed trends fall between the 5th and 95th percentiles of simulated trends, and van Oldenborgh et al. (2013) find that over the 1950–2011 period the pattern of observed grid cell trends agrees with CMIP5 simulated trends to within a combination of

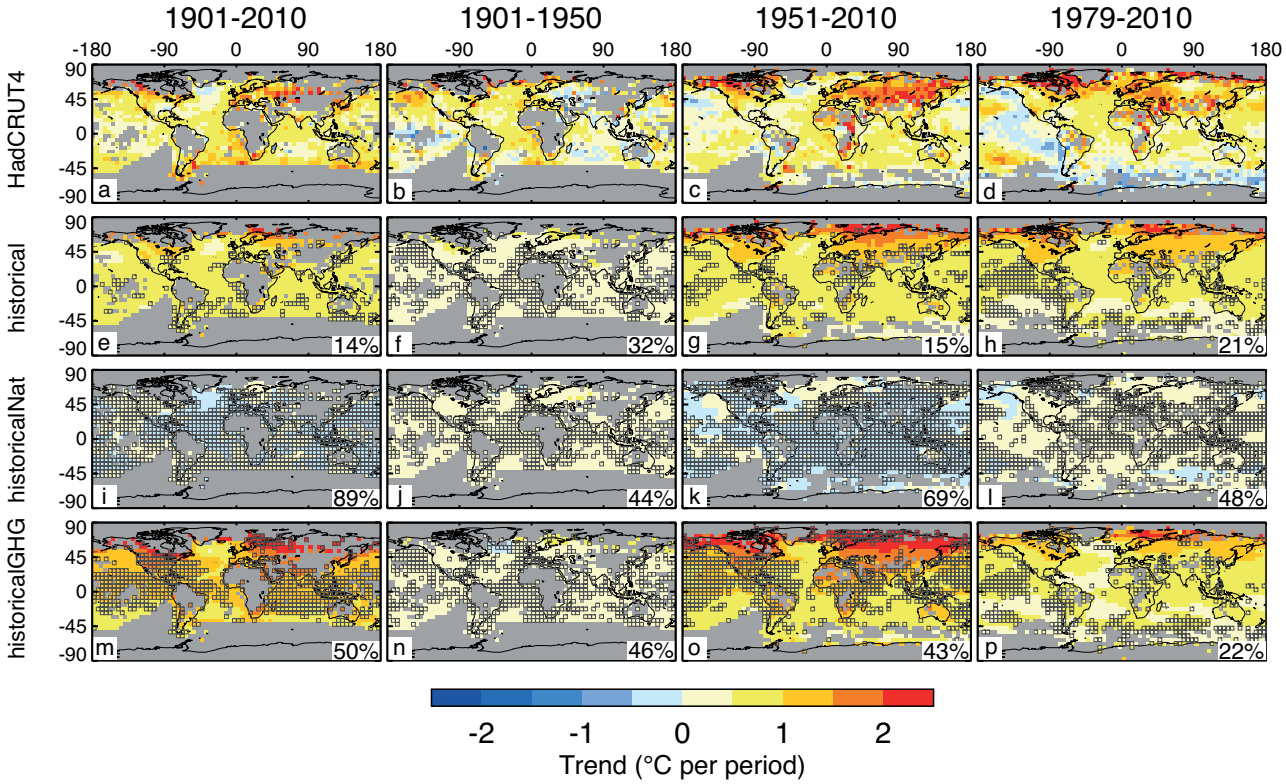

Figure 10.2 | Trends in observed and simulated temperatures (K over the period shown) over the 1901–2010 (a, e, i, m), 1901–1950 (b, f, j, n), 1951–2010 (c, g, k, o) and 1979–2010 (d, h, l, p) periods. Trends in observed temperatures from the Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4) (a–d), CMIP3 and CMIP5 model simulations including anthropogenic and natural forcings (e–h), CMIP3 and CMIP5 model simulations including natural forcings only (i–l) and CMIP3 and CMIP5 model simulations including greenhouse gas forcing only (m–p). Trends are shown only where sufficient observational data are available in the HadCRUT4 data set, and grid cells with insufficient observations to derive trends are shown in grey. Boxes in (e–p) show where the observed trend lies outside the 5 to 95th percentile range of simulated trends, and the ratio of the number of such grid cells to the total number of grid cells with sufficient data is shown as a percentage in the lower right of each panel. (Adapted from Jones et al., 2013.)

model spread and internal variability. Areas of disagreement over the 1901–2010 period include parts of Asia and the Southern Hemisphere (SH) mid-latitudes, where the simulations warm less than the observations, and parts of the tropical Pacific, where the simulations warm more than the observations (Jones et al., 2013; Knutson et al., 2013). Stronger warming in observations than models over parts of East Asia could in part be explained by uncorrected urbanization influence in the observations (Section 2.4.1.3), or by an overestimate of the response to aerosol increases. Trends simulated in response to natural forcings only are generally close to zero, and inconsistent with observed trends in most locations (Figure 10.2i) (see also Knutson et al., 2013). Trends simulated in response to GHG changes only over the 1901–2010 period are larger than those observed at most locations, and in many cases significantly so (Figure 10.2m). This is expected because these simulations do not include the cooling effects of aerosols. Differences in patterns of simulated and observed seasonal mean temperature trends and possible causes are considered in more detail in Box 11.2.

Over the period 1979–2010 most observed regions exhibited warming (Figure 10.2d), but much of the eastern Pacific and Southern Oceans cooled. These regions of cooling are not seen in the simulated trends over this period in response to anthropogenic and natural forcing (Figure 10.2h), which show significantly more warming in much of these regions (Jones et al., 2013; Knutson et al., 2013). This cooling and reduced warming in observations over the Southern Hemisphere mid-latitudes over the 1979–2010 period can also be seen in the zonal mean trends (Figure 10.3d), which also shows that the models tend to warm too much in this region over this period. However, there is no discrepancy in zonal mean temperature trends over the longer 1901–2010 period in this region (Figure 10.3a), suggesting that the discrepancy over the 1979–2010 period either may be an unusually strong manifestation of internal variability in the observations or relate to regionally important forcings over the past three decades which are not included in most CMIP5 simulations, such as sea salt aerosol increases due to strengthened high latitude winds (Korhonen et al., 2010), or sea ice extent increases driven by freshwater input from ice shelf melting (Bintanja et al., 2013). Except at high latitudes, zonal mean trends over the 1901–2010 period in all three data sets are inconsistent with naturally forced trends, indicating a detectable anthropogenic signal in most zonal means over this period (Figure 10.3a). McKitrick and Tole (2012) find that few CMIP3 models have significant explanatory power when fitting the spatial pattern of 1979–2002 trends in surface temperature over land, by which they mean that these models add little or no skill to a fit including the spatial pattern of tropospheric temperature trends as well as the major atmospheric oscillations. This is to be expected, as temperatures in the troposphere are well correlated in the vertical, and local temperature trends over so short a period are dominated by internal variability.

CMIP5 models generally exhibit realistic variability in GMST on decadal to multi-decadal time scales (Jones et al., 2013; Knutson et al., 2013; Section 9.5.3.1, Figure 9.33), although it is difficult to evaluate internal variability on multi-decadal time scales in observations given the shortness of the observational record and the presence of external forcing. The observed trend in GMST since the 1950s is very large compared to model estimates of internal variability (Stott et al., 2010; Drost et al., 2012; Drost and Karoly, 2012). Knutson et al. (2013) compare observed

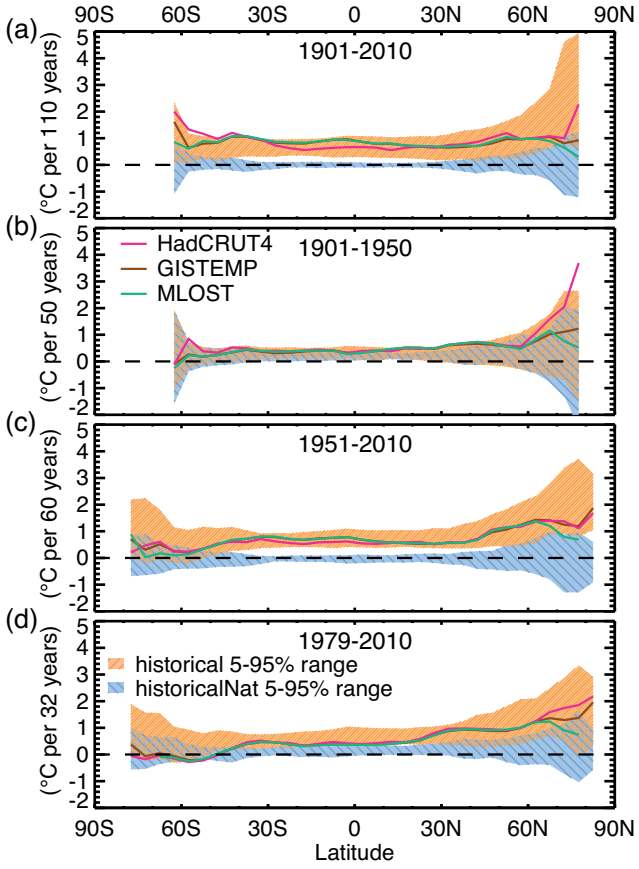

Figure 10.3 | Zonal mean temperature trends over the 1901–2010 (a), 1901–1950 (b), 1951–2010 (c) and 1979–2010 (d) periods. Solid lines show Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4, red), Goddard Institute of Space Studies Surface Temperature Analysis (GISTEMP, brown) and Merged Land–Ocean Surface Temperature Analysis (MLOST, green) observational data sets, orange hatching represents the 90% central range of CMIP3 and CMIP5 simulations with anthropogenic and natural forcings, and blue hatching represents the 90% central range of CMIP3 and CMIP5 simulations with natural forcings only. All model and observations data are masked to have the same coverage as HadCRUT4. (Adapted from Jones et al., 2013.)

trends in GMST with a combination of simulated internal variability and the response to natural forcings and find that the observed trend would still be detected for trends over this period even if the magnitude of the simulated natural variability (i.e., the standard deviation of trends) were tripled.

10.3.1.1.3 Attribution of observed global-scale temperature changes

The evolution of temperature since the start of the global instrumental record

Since the AR4, detection and attribution studies have been carried out using new model simulations with more realistic forcings, and new observational data sets with improved representation of uncertainty (Christidis et al., 2010; Jones et al., 2011, 2013; Gillett et al., 2012, 2013; Stott and Jones, 2012; Knutson et al., 2013; Ribes and Terray, 2013). Although some inconsistencies between the simulated and observed responses to forcings in individual models were identified (Gillett et al., 2013; Jones et al., 2013; Ribes and Terray, 2013) over-

all these results support the AR4 assessment that GHG increases *very likely* caused most (>50%) of the observed GMST increase since the mid-20th century (Hegerl et al., 2007b).

The results of multiple regression analyses of observed temperature changes onto the simulated responses to GHG, other anthropogenic and natural forcings are shown in Figure 10.4 (Gillett et al., 2013; Jones et al., 2013; Ribes and Terray, 2013). The results, based on HadCRUT4 and a multi-model average, show robustly detected responses to GHG in the observational record whether data from 1861–2010 or only from 1951–2010 are analysed (Figure 10.4b). The advantage of analysing the longer period is that more information on observed and modelled changes is included, while a disadvantage is that it is difficult to validate climate models' estimates of internal variability over such a long period. Individual model results exhibit considerable spread among scaling factors, with estimates of warming attributable to each forcing sensitive to the model used for the analsys (Figure 10.4; Gillett et al., 2013; Jones et al., 2013; Ribes and Terray, 2013), the period over which the analysis is applied (Figure 10.4; Gillett et al., 2013; Jones et al., 2013), and the Empirical Orthogonal Function (EOF) truncation or degree of spatial filtering (Jones et al., 2013; Ribes and Terray, 2013). In some cases the GHG response is not detectable in regressions using individual models (Figure 10.4; Gillett et al., 2013; Jones et al., 2013; Ribes and Terray, 2013), or a residual test is failed (Gillett et al., 2013; Jones et al., 2013; Ribes and Terray, 2013), indicating a poor fit between the simulated response and observed changes. Such cases are probably due largely to errors in the spatio-temporal pattern of responses to forcings simulated in individual models (Ribes and Terray, 2013), although observational error and internal variability errors could also play a role. Nonetheless, analyses in which responses are averaged across multiple models generally show much less sensitivity to period and EOF trucation (Gillett et al., 2013; Jones et al., 2013), and more consistent residuals (Gillett et al., 2013), which may be because model response errors are smaller in a multi-model mean.

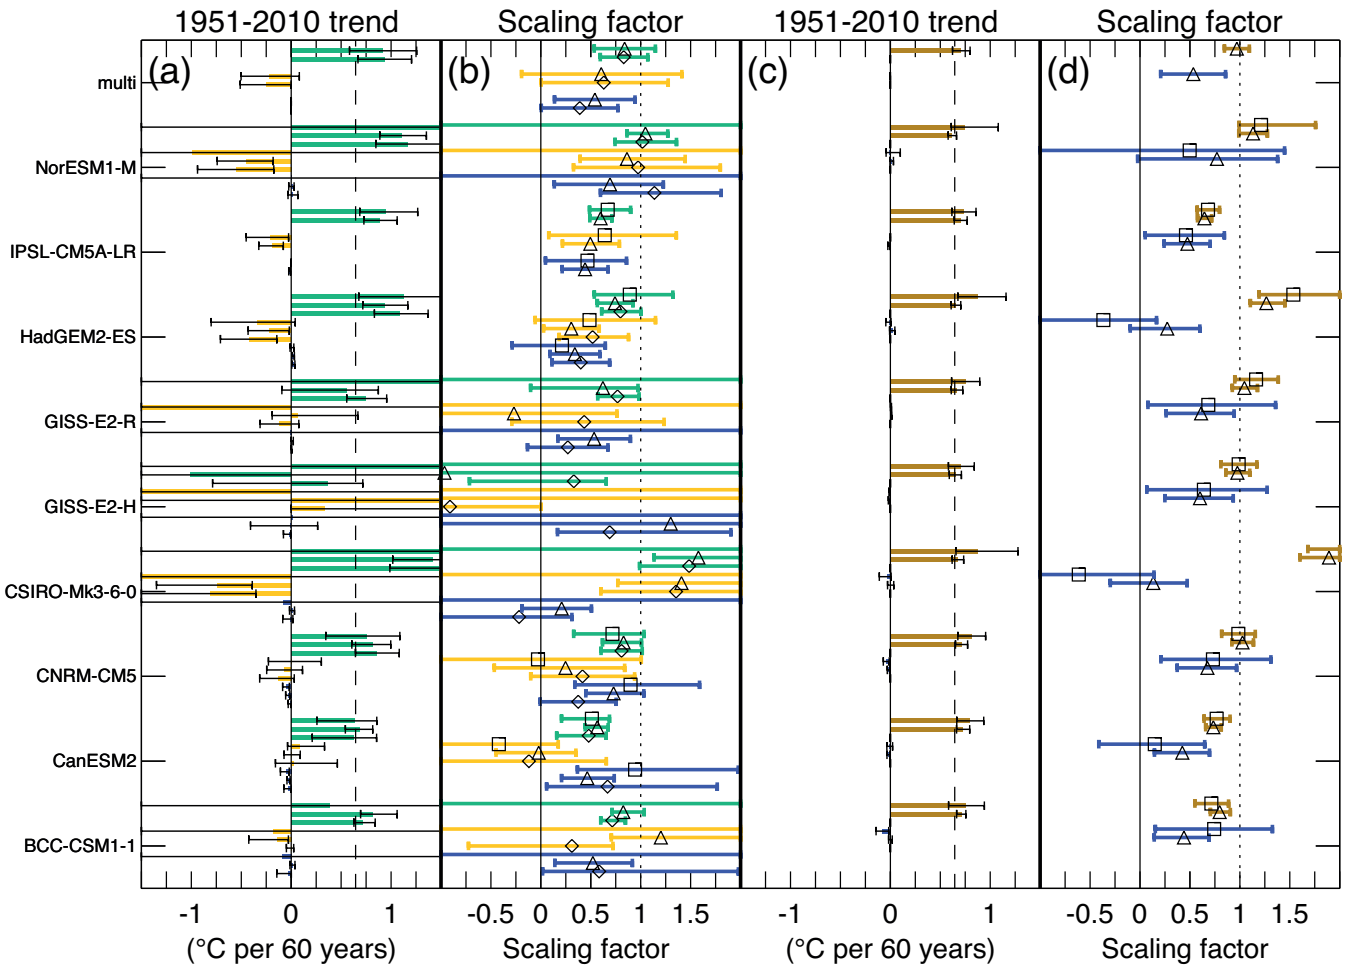

Figure 10.4 | (a) Estimated contributions of greenhouse gas (GHG, green), other anthropogenic (yellow) and natural (blue) forcing components to observed global mean surface temperature (GMST) changes over the 1951–2010 period. (b) Corresponding scaling factors by which simulated responses to GHG (green), other anthropogenic (yellow) and natural forcings (blue) must be multiplied to obtain the best fit to Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4; Morice et al., 2012) observations based on multiple regressions using response patterns from nine climate models individually and multi-model averages (multi). Results are shown based on an analysis over the 1901–2010 period (squares, Ribes and Terray, 2013), an analysis over the 1861–2010 period (triangles, Gillett et al., 2013) and an analysis over the 1951–2010 period (diamonds, Jones et al., 2013). (c, d) As for (a) and (b) but based on multiple regressions estimating the contributions of total anthropogenic forcings (brown) and natural forcings (blue) based on an analysis over 1901–2010 period (squares, Ribes and Terray, 2013) and an analysis over the 1861–2010 period (triangles, Gillett et al., 2013). Coloured bars show best estimates of the attributable trends (a and c) and 5 to 95% confidence ranges of scaling factors (b and d). Vertical dashed lines in (a) and (c) show the best estimate HadCRUT4 observed trend over the period concerned. Vertical dotted lines in (b) and d) denote a scaling factor of unity.

We derive assessed ranges for the attributable contributions of GHGs, other anthropogenic forcings and natural forcings by taking the smallest ranges with a precision of one decimal place that span the 5 to 95% ranges of attributable trends over the 1951–2010 period from the Jones et al. (2013) weighted multi-model analysis and the Gillett et al. (2013) multi-model analysis considering observational uncertainty (Figure 10.4a). The assessed range for the attributable contribution of combined anthropogenic forcings was derived in the same way from the Gillett et al. (2013) multi-model attributable trend and shown in Figure 10.4c. We moderate our likelihood assessment and report *likely* ranges rather than the *very likely* ranges directly implied by these studies in order to account for residual sources of uncertainty including sensitivity to EOF truncation and analysis period (e.g., Ribes and Terray, 2013). In this context, GHGs means well-mixed greenhouse gases (WMGHGs), other anthropogenic forcings means aerosol changes, and in most models ozone changes and land use changes, and natural forcings means solar irradiance changes and volcanic aerosols. Over the 1951–2010 period, the observed GMST increased by approximately 0.6°C. GHG increases *likely* contributed 0.5°C to 1.3°C, other anthropogenic forcings *likely* contributed –0.6°C to 0.1°C and natural forcings *likely* contributed –0.1°C to 0.1°C to observed GMST trends over this period. Internal variability *likely* contributed –0.1°C to 0.1°C to observed trends over this period (Knutson et al., 2013). This assessment is shown schematically in Figure 10.5. The assessment is supported additionally by a complementary analysis in which the parameters of an Earth System Model of Intermediate Complexity (EMIC) were constrained using observations of near-surface temperature and ocean heat content, as well as prior information on the magnitudes of forcings, and which concluded that GHGs have caused 0.6°C to 1.1°C (5 to 95% uncertainty) warming since the mid-20th century (Huber and Knutti, 2011); an analysis by Wigley and Santer (2013), who used an energy balance model and RF and climate sensitivity estimates from AR4, and they concluded that there was about a 93% chance that GHGs caused a warming greater than observed over the 1950–2005 period; and earlier detection and attribution studies assessed in the AR4 (Hegerl et al., 2007b).

The inclusion of additional data to 2010 (AR4 analyses stopped at 1999; Hegerl et al. (2007b)) helps to better constrain the magnitude of the GHG-attributable warming (Drost et al., 2012; Gillett et al., 2012; Stott and Jones, 2012; Gillett et al., 2013), as does the inclusion of spatial information (Stott et al., 2006; Gillett et al., 2013), though Ribes and Terray (2013) caution that in some cases there are inconsistencies between observed spatial patterns of response and those simulated in indvidual models. While Hegerl et al. (2007b) assessed that a significant cooling of about 0.2 °C was attributable to natural forcings over the 1950–1999 period, the temperature trend attributable to natural forcings over the 1951–2010 period is very small (<0.1°C). This is because, while Mt Pinatubo cooled global temperatures in the early 1990s, there have been no large volcanic eruptions since, resulting in small simulated trends in response to natural forcings over the 1951–2010 period (Figure 10.1b). Regression coefficients for natural forcings tend to be smaller than one, suggesting that the response to natural forcings may be overestimated by the CMIP5 models on average (Figure 10.4; Gillett et al., 2013; Knutson et al., 2013). Attribution of observed changes is robust to observational uncertainty which is comparably important to internal climate variability as a source of uncertainty in GHG-attributable warming and aerosol-attributable cooling (Jones and Stott, 2011; Gillett et al., 2013; Knutson et al., 2013). The response to GHGs was detected using Hadley Centre new Global Environmental Model 2-Earth System (HadGEM2-ES; Stott and Jones, 2012), Canadian Earth System Model 2 (CanESM2; Gillett et al., 2012) and other CMIP5 models except for Goddard Institute for Space Studies-E2-H (GISS-E2-H; Gillett et al., 2013; Jones et al., 2013) (Figure 10.4). However, the influence of other anthropogenic forcings was detected only in some CMIP5 models (Figure 10.4). This lack of detection of other anthropogenic forcings compared to detection of an aerosol response using four CMIP3 models over the period 1900–1999 (Hegerl et al., 2007b) does not only relate to the use of data to 2010 rather than 2000 (Stott and Jones, 2012), although this could play a role (Gillett et al., 2013; Ribes and Terray, 2013). Whether it is associated with a cancellation of aerosol cooling by ozone and black carbon (BC) warming in the CMIP5 simulations, making the signal harder to detect, or by some aspect of the response to other anthropogenic forcings that is less realistic in these models is not clear.

Although closely constraining the GHG and other anthropogenic contributions to observed warming remains challenging owing to their degeneracy and sensitivity to methodological choices (Jones et al., 2013; Ribes and Terray, 2013), a total anthropogenic contribution to warming can be much more robustly constrained by a regression of observed temperature changes onto the simulated responses to all anthropogenic forcings and natural forcings (Figure 10.4; Gillett et al., 2013; Ribes and Terray, 2013). Robust detection of anthropogenic influence is also found if a new optimal detection methodology, the Regularised Optimal Fingerprint approach (see Section 10.2; Ribes et al., 2013), is applied (Ribes and Terray, 2013). A better constrained estimate of the total anthropogenic contribution to warming since the mid-20th century than the GHG contribution is also found by Wigley and Santer (2013). Knutson et al. (2013) demonstrate that observed trends in GMST are inconsistent with the simulated response to natural forcings alone, but consistent with the simulated response to natural and anthropogenic forcings for all periods beginning between 1880 and 1990 and ending in 2010, which they interpret as evidence that warming is in part attributable to anthropogenic influence over these periods. Based on the well-constrained attributable anthropogenic trends shown in Figure 10.4 we assess that anthropogenic forcings *likely* contributed 0.6°C to 0.8°C to the observed warming over the 1951–2010 period (Figure 10.5).

There are some inconsistencies in the simulated and observed magnitudes of responses to forcing for some CMIP5 models (Figure 10.4); for example, CanESM2 has a GHG regression coefficient significantly less than 1 and a regression coefficient for other anthropogenic forcings also significantly less than 1 (Gillett et al., 2012; Gillett et al., 2013; Jones et al., 2013; Ribes and Terray, 2013), indicating that this model overestimates the magnitude of the response to GHGs and to other anthropogenic forcings. Averaged over the ensembles of models considered by Gillett et al. (2013) and Jones et al. (2013), the best-estimate GHG and OA scaling factors are less than 1 (Figure 10.4), indicating that the model mean GHG and OA responses should be scaled down to best match observations. The best-estimate GHG scaling factors are larger than the best-estimate OA scaling factors, although the discrepancy from 1 is not significant in either case and the ranges of the GHG

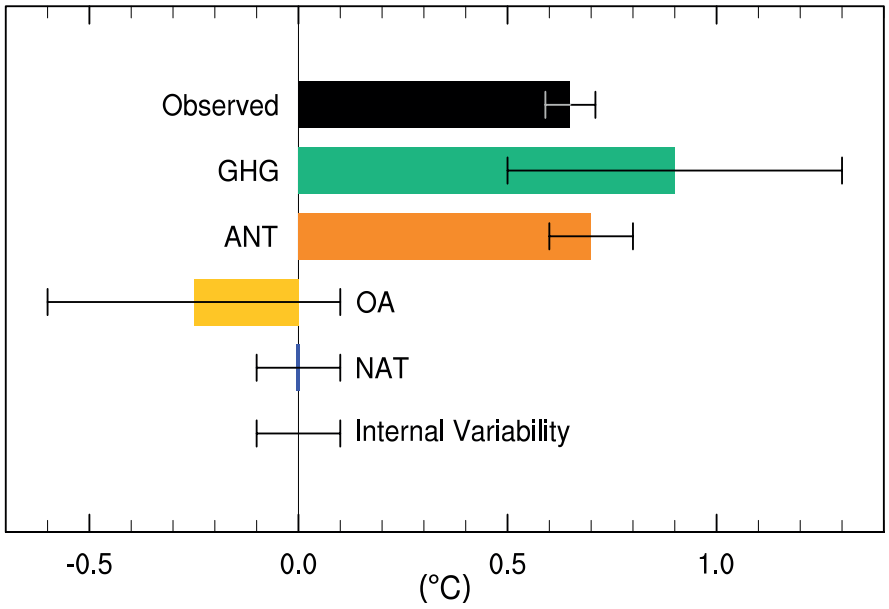

Figure 10.5 | Assessed *likely* ranges (whiskers) and their mid-points (bars) for attributable warming trends over the 1951–2010 period due to well-mixed greenhouse gases, other anthropogenic forcings (OA), natural forcings (NAT), combined anthropogenic forcings (ANT) and internal variability. The Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4) observations are shown in black with the 5 to 95% uncertainty range due to observational uncertainty in this record (Morice et al., 2012).

and OA scaling factors are overlapping. Overall there is some evidence that some CMIP5 models have a higher transient response to GHGs and a larger response to other anthropogenic forcings (dominated by the effects of aerosols) than the real world (*medium confidence*). Inconsistencies between simulated and observed trends in GMST were also identified in several CMIP3 models by Fyfe et al. (2010) after removing volcanic, El Niño-Southern Oscillation (ENSO), and Cold Ocean/Warm Land pattern (COWL) signals from GMST, although uncertainties may have been underestimated because residuals were modelled by a first-order autoregressive processes. A longer observational record and a better understanding of the temporal changes in forcing should make it easier to identify discrepancies between the magnitude of the observed response to a forcing, and the magnitude of the response simulated in individual models. To the extent that inconsistencies between simulated and observed changes are independent between models, this issue may be addressed by basing our assessment on attribution analyses using the mean response from multiple models, and by accounting for model uncertainty when making such assessments.

In conclusion, although some inconsistencies in the forced responses of individual models and observations have been identified, the detection of the global temperature response to GHG increases using average responses from multiple models is robust to observational uncertainty and methodological choices. It is supported by basic physical arguments. We conclude, consistent with Hegerl et al. (2007b), that more than half of the observed increase in GMST from 1951 to 2010 is *very likely* due to the observed anthropogenic increase in GHG concentrations.

The influence of BC aerosols (from fossil and biofuel sources) has been detected in the recent global temperature record in one analysis, although the warming attributable to BC by Jones et al. (2011) is small compared to that attributable to GHG increases. This warming is simulated mainly over the Northern Hemisphere (NH) with a sufficiently distinct spatio-temporal pattern that it could be separated from the response to other forcings in this study.

Several recent studies have used techniques other than regression-based detection and attribution analyses to address the causes of recent global temperature changes. Drost and Karoly (2012) demonstrated that observed GMST, land–ocean temperature contrast, meridional temperature gradient and annual cycle amplitude exhibited trends over the period 1956–2005 that were outside the 5 to 95% range of simulated internal variability in eight CMIP5 models, based on three different observational data sets. They also found that observed trends in GMST and land–ocean temperature contrast were larger than those simulated in any of 36 CMIP5 simulations with natural forcing only. Drost et al. (2012) found that 1961–2010 trends in GMST and land–ocean temperature contrast were significantly larger than simulated internal variability in eight CMIP3 models. By comparing observed GMST with simple statistical models, Zorita et al. (2008) concluded that there is a very low probability that observed clustering of very warm years in the last decade occurred by chance. Smirnov and Mokhov (2009), adopting an approach that allowed them to distinguish between conventional Granger causality and a 'long-term causality' that focuses on low-frequency changes (see Section 10.2), found that increasing CO_2 concentrations are the principal determining factor in the rise of GMST over recent decades. Sedlacek and Knutti (2012) found that the spatial patterns of sea surface temperature (SST) trends from simulations forced with increases in GHGs and other anthropogenic forcings agree well with observations but differ from warming patterns associated with internal variability.

Several studies that have aimed to separate forced surface temperature variations from those associated with internal variability have identified the North Atlantic as a dominant centre of multi-decadal

internal variability, and in particular modes of variability related to the Atlantic Multi-decadal Oscillation (AMO; Section 14.7.6). The AMO index is defined as an area average of North Atlantic SSTs, and it has an apparent period of around 70 years, which is long compared to the length of observational record making it difficult to deduce robust conclusions about the role of the AMO from only two cycles. Nevertheless, several studies claim a role for internal variability associated with the AMO in driving enhanced warming in the 1980s and 1990s as well as the recent slow down in warming (Box 9.2), while attributing long-term warming to anthropogenically forced variations either by analysing time series of GMST, forcings and indices of the AMO (Rohde et al., 2013; Tung and Zhou, 2013; Zhou and Tung, 2013a) or by analysing both spatial and temporal patterns of temperature (Swanson et al., 2009; DelSole et al., 2011; Wu et al., 2011). Studies based on global mean time series could risk falsely attributing variability to the AMO when variations in external forcings, for example, associated with aerosols, could also cause similar variability. In contrast, studies using space–time patterns seek to distinguish the spatial structure of temperature anomalies associated with the AMO from those associated with forced variability. Unforced climate simulations indicate that internal multi-decadal variability in the Atlantic is characterized by surface anomalies of the same sign from the equator to the high latitudes, with maximum amplitudes in subpolar regions (Delworth and Mann, 2000; Latif et al., 2004; Knight et al., 2005; DelSole et al., 2011) while the net response to anthropogenic and natural forcing over the 20th century, such as observed temperature change, is characterized by warming nearly everywhere on the globe, but with minimum warming or even cooling in the subpolar regions of the North Atlantic (Figure 10.2; Ting et al., 2009; DelSole et al., 2011).

Some studies implicate tropospheric aerosols in driving decadal variations in Atlantic SST (Evan et al., 2011; Booth et al., 2012; Terray, 2012), and temperature variations in eastern North America (Leibensperger et al., 2012). Booth et al. (2012) find that most multi-decadal variability in North Atlantic SSTs is simulated in one model mainly in response to aerosol variations, although its simulated changes in North Atlantic ocean heat content and salinity have been shown to be inconsistent with observations (Zhang et al., 2012). To the extent that climate models simulate realistic internal variability in the AMO (Section 9.5.3.3.2), AMO variability is accounted for in uncertainty estimates from regression-based detection and attribution studies (e.g., Figure 10.4).

To summarize, recent studies using spatial features of observed temperature variations to separate AMO variability from externally forced changes find that detection of external influence on global temperatures is not compromised by accounting for AMO-congruent variability (*high confidence*). There remains some uncertainty about how much decadal variability of GMST that is attributed to AMO in some studies is actually related to forcing, notably from aerosols. There is agreement among studies that the contribution of the AMO to global warming since 1951 is very small (considerably less than 0.1°C; see also Figure 10.6) and given that observed warming since 1951 is very large compared to climate model estimates of internal variability (Section 10.3.1.1.2), which are assessed to be adequate at global scale (Section 9.5.3.1), we conclude that it is *virtually certain* that internal variability alone cannot account for the observed global warming since 1951.

Box 10.2 | The Sun's Influence on the Earth's Climate

A number of studies since AR4 have addressed the possible influences of long-term fluctuations of solar irradiance on past climates, particularly related to the relative warmth of the Medieval Climate Anomaly (MCA) and the relative coolness in the Little Ice Age (LIA). There is *medium confidence* that both external solar and volcanic forcing, and internal variability, contributed substantially to the spatial patterns of surface temperature changes between the MCA and the LIA, but *very low confidence* in quantitative estimates of their relative contributions (Sections 5.3.5.3 and 5.5.1). The combined influence of volcanism, solar forcing and a small drop in greenhouse gases (GHGs) *likely* contributed to Northern Hemisphere cooling during the LIA (Section 10.7.2). Solar radiative forcing (RF) from the Maunder Minimum (1745) to the satellite era (average of 1976–2006) has been estimated to be +0.08 to +0.18 W m^{-2} (*low confidence*, Section 8.4.1.2). This may have contributed to early 20th century warming (*low confidence*, Section 10.3.1).

More recently, it is *extremely unlikely* that the contribution from solar forcing to the observed global warming since 1950 was larger than that from GHGs (Section 10.3.1.1.3). It is *very likely* that there has been a small decrease in solar forcing of –0.04 [–0.08 to 0.00] W m^{-2} over a period with direct satellite measurements of solar output from 1986 to 2008 (Section 8.4.1.1). There is *high confidence* that changes in total solar irradiance have not contributed to global warming during that period.

Since AR4, there has been considerable new research that has connected solar forcing to climate. The effect of solar forcing on GMST trends has been found to be small, with less than 0.1°C warming attributable to combined solar and volcanic forcing over the 1951–2010 period (Section 10.3.1), although the 11-year cycle of solar variability has been found to have some influence on GMST variability over the 20th century. GMST changes between solar maxima and minima are estimated to be of order 0.1°C from some regression studies of GMST and forcing estimates (Figure 10.6), although several studies have suggested these results may be too large owing to issues including degeneracy between forcing and with internal variability, overfitting of forcing indices and underestimated uncertainties in responses (Ingram, 2007; Benestad and Schmidt, 2009; Stott and Jones, 2009). Climate models generally show less than half this variability (Jones et al., 2012). *(continued on next page)*

Box 10.2 (continued)

Variability associated with the 11-year solar cycle has also been shown to produce measurable short-term regional and seasonal climate anomalies (Miyazaki and Yasunari, 2008; Gray et al., 2010; Lockwood, 2012; National Research Council, 2012) particularly in the Indo-Pacific, Northern Asia and North Atlantic regions (*medium evidence*). For example, studies have suggested an 11-year solar response in the Indo-Pacific region in which the equatorial eastern Pacific sea surface temperatures (SSTs) tend to be below normal, the sea level pressure (SLP) in the Gulf of Alaska and the South Pacific above normal, and the tropical convergence zones on both hemispheres strengthened and displaced polewards under solar maximum conditions, although it can be difficult to discriminate the solar-forced signal from the El Niño-Southern Oscillation (ENSO) signal (van Loon et al., 2007; van Loon and Meehl, 2008; White and Liu, 2008; Meehl and Arblaster, 2009; Roy and Haigh, 2010, 2012; Tung and Zhou, 2010; Bal et al., 2011; Haam and Tung, 2012; Hood and Soukharev, 2012; Misios and Schmidt, 2012). For northern summer, there is evidence that for peaks in the 11-year solar cycle, the Indian monsoon is intensified (Kodera, 2004; van Loon and Meehl, 2012), with solar variability affecting interannual connections between the Indian and Pacific sectors due to a shift in the location of the descending branch of the Walker Circulation (Kodera et al., 2007). In addition, model sensitivity experiments (Ineson et al., 2011) suggest that the negative phase of the North Atlantic Oscillation (NAO) is more prevalent during solar minima and there is some evidence of this in observations, including an indication of increased frequency of high-pressure 'blocking' events over Europe in winter (Barriopedro et al., 2008; Lockwood et al., 2010; Woollings et al., 2010).

Two mechanisms have been identified in observations and simulated with climate models that could explain these low amplitude regional responses (Gray et al., 2010; *medium evidence*). These mechanisms are additive and may reinforce one another so that the response to an initial small change in solar irradiance is amplified regionally (Meehl et al., 2009). The first mechanism is a top-down mechanism first noted by Haigh (1996) where greater solar ultraviolet radiation (UV) in peak solar years warms the stratosphere directly via increased radiation and indirectly via increased ozone production. This can result in a chain of processes that influences deep tropical convection (Balachandran et al., 1999; Shindell et al., 1999; Kodera and Kuroda, 2002; Haigh et al., 2005; Kodera, 2006; Matthes et al., 2006). In addition, there is less heating than average in the tropical upper stratosphere under solar minimum conditions which weakens the equator-to-pole temperature gradient. This signal can propagate downward to weaken the tropospheric mid-latitude westerlies, thus favoring a negative phase of the Arctic Oscillation (AO) or NAO. This response has been shown in several models (e.g., Shindell et al., 2001; Ineson et al., 2011) though there is no significant AO or NAO response to solar irradiance variations on average in the CMIP5 models (Gillett and Fyfe, 2013).

The second mechanism is a bottom-up mechanism that involves coupled air–sea radiative processes in the tropical and subtropical Pacific that also influence convection in the deep tropics (Meehl et al., 2003, 2008; Rind et al., 2008; Bal et al., 2011; Cai and Tung, 2012; Zhou and Tung, 2013b). Such mechanisms have also been shown to influence regional temperatures over longer time scales (decades to centuries), and can help explain patterns of regional temperature changes seen in paleoclimate data (e.g., Section 10.7.2; Mann et al., 2009; Goosse et al., 2012b) although they have little effect on global or hemispheric mean temperatures at either short or long time scales.

A possible amplifying mechanism linking solar variability and the Earth's climate system via cosmic rays has been postulated. It is proposed that variations in the cosmic ray flux associated with changes in solar magnetic activity affect ion-induced aerosol nucleation and cloud condensation nuclei (CCN) production in the troposphere (Section 7.4.6). A strong solar magnetic field would deflect cosmic rays and lead to fewer CCN and less cloudiness, thereby allowing for more solar energy into the system. Since AR4, there has been further evidence to disprove the importance of this amplifying mechanism. Correlations between cosmic ray flux and observed aerosol or cloud properties are weak and local at best, and do not prove to be robust on the regional or global scale (Section 7.4.6). Although there is some evidence that ionization from cosmic rays may enhance aerosol nucleation in the free troposphere, there is *medium evidence and high agreement* that the cosmic ray–ionization mechanism is too weak to influence global concentrations of CCN or their change over the last century or during a solar cycle in any climatically significant way (Sections 7.4.6 and 8.4.1.5). The lack of trend in cosmic ray intensity over the 1960–2005 period (McCracken and Beer, 2007) provides another argument against the hypothesis of a major contribution of cosmic ray variations to the observed warming over that period given the existence of short time scales in the climate system response.

Thus, although there is *medium confidence* that solar variability has made contributions to past climate fluctuations, since the mid-20th century there has been little trend in solar forcing. There are at least two amplifying mechanisms that have been proposed and simulated in some models that could explain small observed regional and seasonal climate anomalies associated with the 11-year solar cycle, mostly in the Indo-Pacific region and northern mid to high latitudes.

Regarding possible future influences of the sun on the Earth's climate, there is *very low confidence* in our ability to predict future solar output, but there is *high confidence* that the effects from solar irradiance variations will be much smaller than the projected climate changes from increased RF due to GHGs (Sections 8.4.1.3 and 11.3.6.2.2).

Based on a range of detection and attribution analyses using multiple solar irradiance reconstructions and models, Hegerl et al. (2007b) concluded that it is *very likely* that GHGs caused more global warming than solar irradiance variations over the 1950–1999 period. Detection and attribution analyses applied to the CMIP5 simulations (Figure 10.4) indicate less than 0.1°C temperature change attributable to combined solar and volcanic forcing over the 1951–2010 period. Based on a regression of paleo temperatures onto the response to solar forcing simulated by an energy balance model, Scafetta and West (2007) find that up to 50% of the warming since 1900 may be solar-induced, but Benestad and Schmidt (2009) show this conclusion is not robust, being based on disregarding forcings other than solar in the preindustrial period, and assuming a high and precisely known value for climate sensitivity. Despite claims that more than half the warming since 1970 can be ascribed to solar variability (Loehle and Scaffetta, 2011) , a conclusion based on an incorrect assumption of no anthropogenic influence before 1950 and a 60-year solar cycle influence on global temperature (see also Mazzarella and Scafetta, 2012), several studies show that solar variations cannot explain global mean surface warming over the past 25 years, because solar irradiance has declined over this period (Lockwood and Fröhlich, 2007, 2008; Lockwood, 2008, 2012). Lean and Rind (2008) conclude that solar forcing explains only 10% of the warming over the past 100 years, while contributing a small cooling over the past 25 years. Thus while there is some evidence for solar influences on regional climate variability (Box 10.2) solar forcing has only had a small effect on GMST. Overall, we conclude that it is *extremely unlikely* that the contribution from solar forcing to the warming since 1950 was larger than that from GHGs.

A range of studies have used statistical methods to separate out the influence of known sources of internal variability, including ENSO and, in some cases, the AMO, from the response to external drivers, including volcanoes, solar variability and anthropogenic influence, in the recent GMST record: see, for example, Lockwood (2008), Lean and Rind (2009), Folland et al. (2013), Foster and Rahmstorf (2011) and Kaufmann et al. (2011). Representative results, as summarized in Imbers et al. (2013), are shown in Figure 10.6. These consistently attribute most of the warming over the past 50 years to anthropogenic influence, even allowing for potential confounding factors like the AMO. While results of such statistical approaches are sensitive to assumptions regarding the properties of both responses to external drivers and internal variability (Imbers et al., 2013), they provide a complementary approach to attribution studies based on global climate models.

Overall, given that the anthropogenic increase in GHGs *likely* caused 0.5°C to 1.3°C warming over 1951–2010, with other anthropogenic forcings probably contributing counteracting cooling, that the effects of natural forcings and natural internal variability are estimated to be small, and that well-constrained and robust estimates of net anthropogenic warming are substantially more than half the observed warming (Figure 10.4) we conclude that it is *extremely likely* that human activities caused more than half of the observed increase in GMST from 1951 to 2010.

The early 20th century warming

The instrumental GMST record shows a pronounced warming during the first half of the 20th century (Figure 10.1a). Correction of residual biases in SST observations leads to a higher estimate of 1950s temperatures, but does not substantially change the warming between 1900 and 1940 (Morice et al., 2012). The AR4 concluded that 'the early 20th century warming is *very likely* in part due to external forcing' (Hegerl et al., 2007b), and that it is *likely* that anthropogenic forcing contributed to this warming. This assessment was based on studies including Shiogama et al. (2006) who find a contribution from solar and volcanic forcing to observed warming to 1949, and Min and Hense (2006), who find strong evidence for a forced (either natural or combined natural and anthropogenic) contribution to global warming from 1900 to 1949. Ring et al. (2012) estimate, based on time series analysis, that part of the early 20th century warming was due to GHG increases (see also Figure 10.6), but find a dominant contribution by internal variability. CMIP5 model simulations of the historical period show forced warming over the early 20th century (Figure 10.1a), consistent with earlier detection and attribution analyses highlighted in the AR4 and TAR. The early 20th century contributes to the detection of external forcings over the 20th century estimated by detection and attribution results (Figure 10.4; Gillett et al., 2013; Ribes and Terray, 2013) and to the detected change over the last millennium to 1950 (see Figure 10.19; Schurer et al., 2013).

The pattern of warming and residual differences between models and observations indicate a role for circulation changes as a contributor to early 20th cenury warming (Figure 10.2), and the contribution of internal variability to the early 20th century warming has been analysed in several publications since the AR4. Crook and Forster (2011) find that the observed 1918–1940 warming was significantly greater than that simulated by most of the CMIP3 models. A distinguishing feature of the early 20th century warming is its pattern (Brönnimann, 2009) which shows the most pronounced warming in the Arctic during the cold season, followed by North America during the warm season, the North Atlantic Ocean and the tropics. In contrast, there was no unusual warming in Australia among other regions (see Figure 10.2b). Such a pronounced pattern points to a role for circulation change as a contributing factor to the regional anomalies contributing to this warming. Some studies have suggested that the warming is a response to the AMO (Schlesinger and Ramankutty, 1994; Polyakov et al., 2005; Knight et al., 2006; Tung and Zhou, 2013), or a large but random expression of internal variability (Bengtsson et al., 2006; Wood and Overland, 2010). Knight et al. (2009) diagnose a shift from the negative to the positive phase of the AMO from 1910 to 1940, a mode of circulation that is estimated to contribute approximately 0.1°C, trough to peak, to GMST (Knight et al., 2005). Nonetheless, these studies do not challenge the AR4 assessment that external forcing *very likely* made a contribution to the warming over this period. In conclusion, the early 20th century warming is *very unlikely* to be due to internal variability alone. It remains difficult to quantify the contribution to this warming from internal variability, natural forcing and anthropogenic forcing, due to forcing and response uncertainties and incomplete observational coverage.

Year-to-year and decade-to-decade variability of global mean surface temperature

Time series analyses, such as those shown in Figure 10.6, seek to partition the variability of GMST into components attributable to anthropogenic and natural forcings and modes of internal variability such as ENSO and the AMO. Although such time series analyses support

the major role of anthropogenic forcings, particularly due to increasing GHG concentrations, in contributing to the overall warming over the last 60 years, many factors, in addition to GHGs, including changes in tropospheric and stratospheric aerosols, stratospheric water vapour and solar output, as well as internal modes of variability, contribute to the year-to-year and decade-to-decade variability of GMST (Figure 10.6). Detailed discussion of the evolution of GMST of the past 15 years since 1998 is contained in Box 9.2.

10.3.1.1.4 Attribution of regional surface temperature change

Anthropogenic influence on climate has been robustly detected on the global scale, but for many applications an estimate of the anthropogenic contribution to recent temperature trends over a particular region is more useful. However, detection and attribution of climate change at continental and smaller scales is more difficult than on the global scale for several reasons (Hegerl et al., 2007b; Stott et al., 2010).

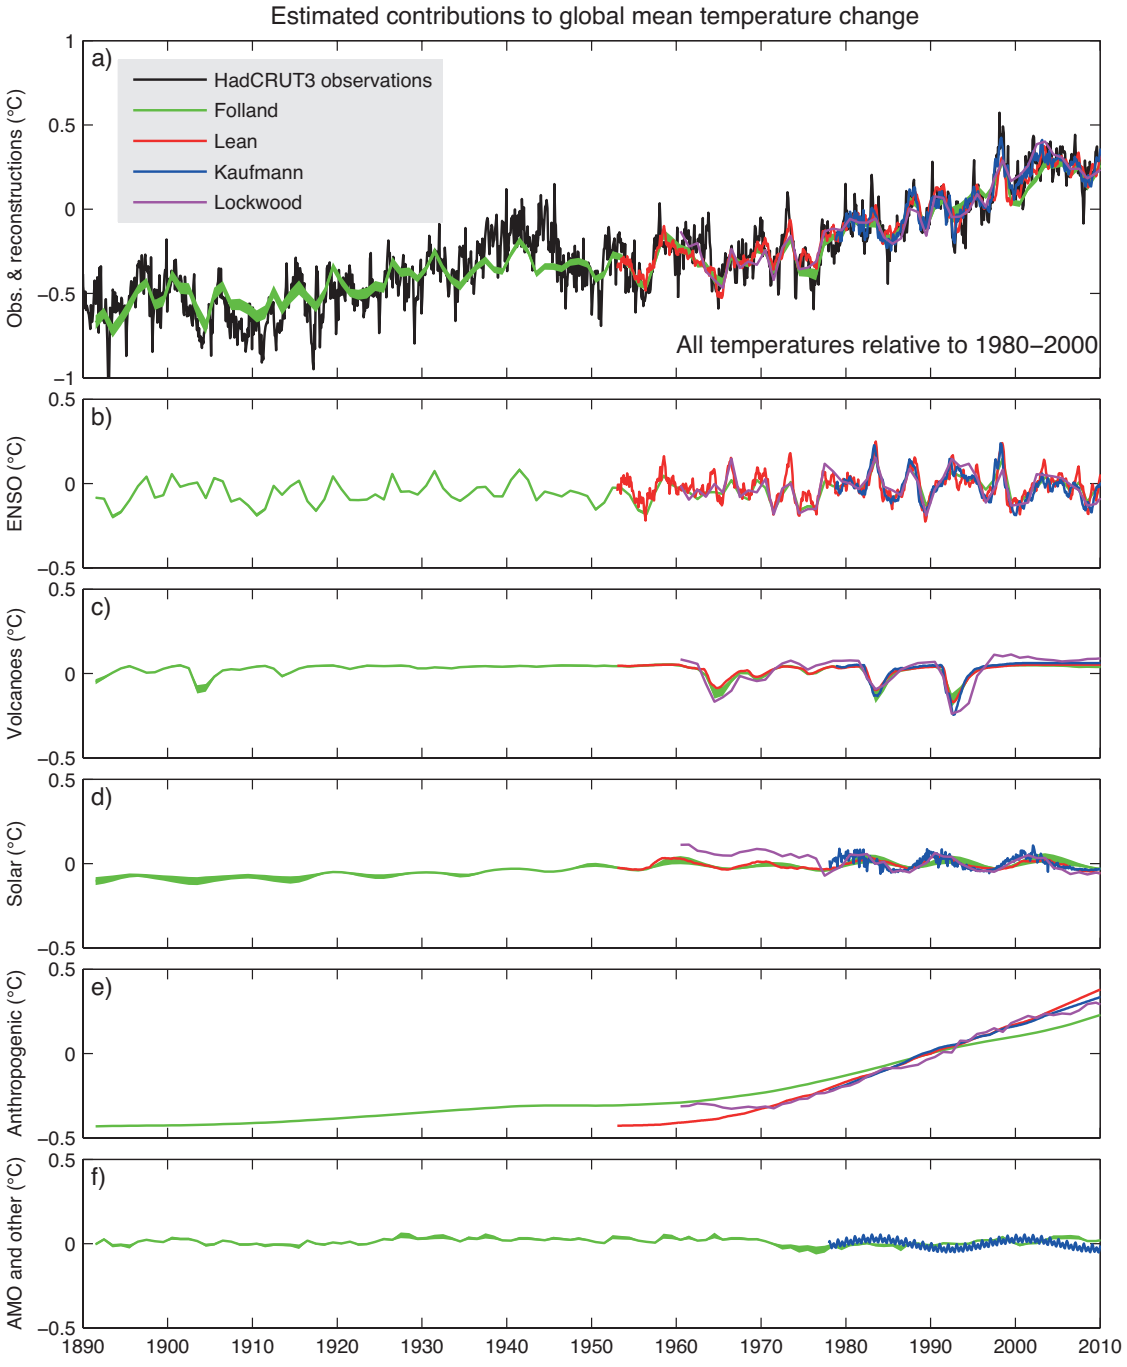

Figure 10.6 | (Top) The variations of the observed global mean surface temperature (GMST) anomaly from Hadley Centre/Climatic Research Unit gridded surface temperature data set version 3 (HadCRUT3, black line) and the best multivariate fits using the method of Lean (red line), Lockwood (pink line), Folland (green line) and Kaufmann (blue line). (Below) The contributions to the fit from (a) El Niño-Southern Oscillation (ENSO), (b) volcanoes, (c) solar forcing, (d) anthropogenic forcing and (e) other factors (Atlantic Multi-decadal Oscillation (AMO) for Folland and a 17.5-year cycle, semi-annual oscillation (SAO), and Arctic Oscillation (AO) from Lean). (From Lockwood (2008), Lean and Rind (2009), Folland et al. (2013) and Kaufmann et al. (2011), as summarized in Imbers et al. (2013).)

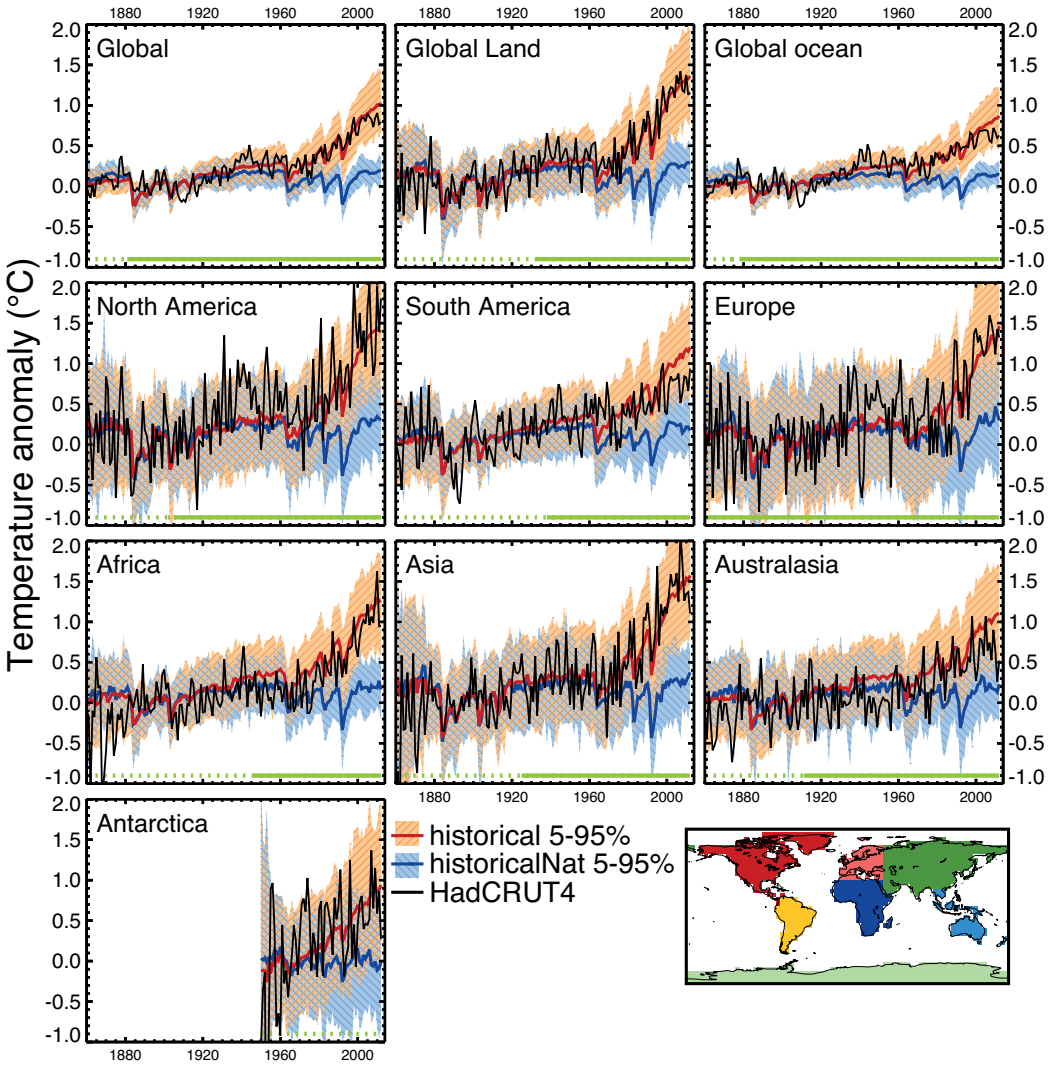

Figure 10.7 | Global, land, ocean and continental annual mean temperatures for CMIP3 and CMIP5 historical (red) and historicalNat (blue) simulations (multi-model means shown as thick lines, and 5 to 95% ranges shown as thin light lines) and for Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4, black). Mean temperatures are shown for Antarctica and six continental regions formed by combining the sub-continental scale regions defined by Seneviratne et al. (2012). Temperatures are shown with respect to 1880–1919 for all regions apart from Antarctica where temperatures are shown with respect to 1950–2010. (Adapted from Jones et al., 2013.)

First, the relative contribution of internal variability compared to the forced response to observed changes tends to be larger on smaller scales, as spatial differences in internal variations are averaged out in large-scale means. Second, because the patterns of response to climate forcings tend to be large scale, there is less spatial information to help distinguish between the responses to different forcings when attention is restricted to a sub-global area. Third, forcings omitted in some global climate model simulations may be important on regional scales, such as land use change or BC aerosol. Lastly, simulated internal variability and responses to forcings may be less reliable on smaller scales than on the global scale. Knutson et al. (2013) find a tendency for CMIP5 models to overestimate decadal variability in the NH extratropics in individual grid cells and underestimate it elsewhere, although Karoly and Wu (2005) and Wu and Karoly (2007) find that variability is not generally underestimated in earlier generation models.

Based on several studies, Hegerl et al. (2007b) concluded that 'it is *likely* that there has been a substantial anthropogenic contribution to surface temperature increases in every continent except Antarctica since the middle of the 20th century'. Figure 10.7 shows comparisons of observed continental scale temperatures (Morice et al., 2012) with CMIP5 simulations including both anthropogenic and natural forcings (red lines) and including just natural forcings (blue lines). Observed temperatures are largely within the range of simulations with anthropogenic forcings for all regions and outside the range of simulations with only natural forcings for all regions except Antarctica (Jones et al., 2013). Averaging over all observed locations, Antarctica has warmed over the 1950–2008 period (Section 2.4.1.1; Gillett et al., 2008b; Jones et al., 2013), even though some individual locations have cooled, particularly in summer and autumn, and over the shorter 1960–1999 period (Thompson and Solomon, 2002; Turner et al., 2005). When temperature changes associated with changes in the Southern Annular Mode are removed by regression, both observations and model simulations indicate warming at all observed locations except the South Pole over the 1950–1999 period (Gillett et al., 2008b). An analysis of Antarctic land temperatures over the period 1950–1999

detected separate natural and anthropogenic responses of consistent magnitude in simulations and observations (Gillett et al., 2008b). Thus anthropogenic influence on climate has now been detected on all seven continents. However the evidence for human influence on Antarctic temperature is much weaker than for the other six continental regions. There is only one attribution study for this region, and there is greater observational uncertainty than the other regions, with very few data before 1950, and sparse coverage that is mainly limited to the coast and the Antarctic Peninsula. As a result of the observational uncertainties, there is *low confidence* in Antarctic region land surface air temperatures changes (Section 2.4.1.1) and we conclude for Antarctica there is *low confidence* that anthropogenic influence has contributed to the observed warming averaged over available stations.

Since the publication of the AR4 several other studies have applied attribution analyses to continental and sub-continental scale regions. Min and Hense (2007) applied a Bayesian decision analysis technique to continental-scale temperatures using the CMIP3 multi-model ensemble and concluded that forcing combinations including GHG increases provide the best explanation of 20th century observed changes in temperature on every inhabited continent except Europe, where the observational evidence is not decisive in their analysis. Jones et al. (2008) detected anthropogenic influence on summer temperatures over all NH continents and in many subcontinental NH land regions in an optimal detection analysis that considered the temperature responses to anthropogenic and natural forcings. Christidis et al. (2010) used a multi-model ensemble constrained by global-scale observed temperature changes to estimate the changes in probability of occurrence of warming or cooling trends over the 1950–1997 period over various sub-continental scale regions. They concluded that the probability of occurrence of warming trends had been at least doubled by anthropogenic forcing over all such regions except Central North America. The estimated distribution of warming trends over the Central North America region was approximately centred on the observed trend, so no inconsistency between simulated and observed trends was identified there. Knutson et al. (2013) demonstrated that observed temperature trends from the beginning of the observational record to 2010 averaged over Europe, Africa, Northern Asia, Southern Asia, Australia and South America are all inconsistent with the simulated response to natural forcings alone, and consistent with the simulated response to combined natural and anthropogenic forcings in the CMIP5 models. They reached a similar conclusion for the major ocean basins with the exception of the North Atlantic, where variability is high.

Several recent studies have applied attribution analyses to specific sub-continental regions. Anthropogenic influence has been found in winter minimum temperature over the western USA (Bonfils et al., 2008; Pierce et al., 2009), a conclusion that is found to be robust to weighting models according to various aspects of their climatology (Pierce et al., 2009); anthropogenic influence has been found in temperature trends over New Zealand (Dean and Stott, 2009) after circulation-related variability is removed as in Gillett et al. (2000); and anthropogenic influence has been found in temperature trends over France, using a first-order autoregressive model of internal variability (Ribes et al., 2010). Increases in anthropogenic GHGs were found to be the main driver of the 20th-century SST increases in both Atlantic and Pacific tropical cyclogenesis regions (Santer et al., 2006; Gillett et al., 2008a). Over both regions, the response to anthropogenic forcings is detected when the response to natural forcings is also included in the analysis (Gillett et al., 2008a). Knutson et al. (2013) detect an anthropogenic influence over Canada, but not over the continental USA, Alaska or Mexico.

Gillett et al. (2008b) detect anthropogenic influence on near-surface Arctic temperatures over land, with a consistent magnitude in simulations and observations. Wang et al. (2007) also find that observed Arctic warming is inconsistent with simulated internal variability. Both studies ascribe Arctic warmth in the 1930s and 1940s largely to internal variability. Shindell and Faluvegi (2009) infer a large contribution to both mid-century Arctic cooling and late century warming from aerosol forcing changes, with GHGs the dominant driver of long-term warming, though they infer aerosol forcing changes from temperature changes using an inverse approach which may lead to some changes associated with internal variability being attributed to aerosol forcing. We therefore conclude that despite the uncertainties introduced by limited observational coverage, high internal variability, modelling uncertainties (Crook et al., 2011) and poorly understood local forcings, such as the effect of BC on snow, there is sufficiently strong evidence to conclude that it is *likely* that there has been an anthropogenic contribution to the very substantial warming in Arctic land surface temperatures over the past 50 years.

Some attribution analyses have considered temperature trends at the climate model grid box scale. At these spatial scales robust attribution is difficult to obtain, since climate models often lack the processes needed to simulate regional details realistically, regionally important forcings may be missing in some models and observational uncertainties are very large for some regions of the world at grid box scale (Hegerl et al., 2007b; Stott et al., 2010). Nevertheless an attribution analysis has been carried out on Central England temperature, a record that extends back to 1659 and is sufficiently long to demonstrate that the representation of multi-decadal variability in the single grid box in the model used, Hadley Centre climate prediction model 3 (HadCM3) is adequate for detection (Karoly and Stott, 2006). The observed trend in Central England Temperature is inconsistent with either internal variability or the simulated response to natural forcings, but is consistent with the simulated response when anthropogenic forcings are included (Karoly and Stott, 2006).

Observed 20th century grid cell trends from Hadley Centre/Climatic Research Unit gridded surface temperature data set 2v (HadCRUT2v; Jones et al., 2001) are inconsistent with simulated internal variability at the 10% significance level in around 80% of grid cells even using HadCM2 which was found to overestimate variability in 5-year mean temperatures at most latitudes (Karoly and Wu, 2005). Sixty percent of grid cells were found to exhibit significant warming trends since 1951, a much larger number than expected by chance (Karoly and Wu, 2005; Wu and Karoly, 2007), and similar results apply when circulation-related variability is first regressed out (Wu and Karoly, 2007). However, as discussed in the AR4 (Hegerl et al., 2007b), when a global field significance test is applied, this becomes a global detection study; since not all grid cells exhibit significant warming trends the overall interpretation of the results in terms of attribution at individual locations remains problematic. Mahlstein et al. (2012) find significant changes in summer season temperatures in about 40% of low-latitude and about 20% of

extratropical land grid cells with sufficient observations, when testing against the null hypothesis of no change in the distribution of summer temperatures. Observed grid cell trends are compared with CMIP5 simulated trends in Figure 10.2i, which shows that in the great majority (89%) of grid cells with sufficient observational coverage, observed trends over the 1901–2010 period are inconsistent with a combination of simulated internal variability and the response to natural forcings (Jones et al., 2013). Knutson et al. (2013) find some deficiencies in the simulation of multi-decadal variability at the grid cell scale in CMIP5 models, but demonstrate that trends at more than 75% of individual grid cells with sufficient observational coverage in HadCRUT4 are inconsistent with the simulated response to natural forcings alone, and consistent or larger than the simulated response to combined anthropogenic and natural forcings in CMIP5 models.

In summary, it is *likely* that anthropogenic forcing has made a substantial contribution to the warming of each of the inhabited continents since 1950. For Antarctica large observational uncertainties result in *low confidence* that anthropogenic influence has contributed to the observed warming averaged over available stations. Anthropogenic influence has *likely* contributed to temperature change in many sub-continental regions. Detection and attribution of climate change at continental and smaller scales is more difficult than at the global scale due to the greater contribution of internal variability, the greater difficulty of distinguishing between different causal factors, and greater errors in climate models' representation of regional details. Nevertheless, statistically significant warming trends are observed at a majority of grid cells, and the observed warming is inconsistent with estimates of possible warming due to natural causes at the great majority of grid cells with sufficient observational coverage.

10.3.1.2 Atmosphere

This section presents an assessment of the causes of global and regional temperature changes in the free atmosphere. In AR4, Hegerl et al. (2007b) concluded that 'the observed pattern of tropospheric warming and stratospheric cooling is *very likely* due to the influence of anthropogenic forcing, particularly greenhouse gases and stratospheric ozone depletion.' Since AR4, insight has been gained into regional aspects of free tropospheric trends and the causes of observed changes in stratospheric temperature.

Atmospheric temperature trends through the depth of the atmosphere offer the possibility of separating the effects of multiple climate forcings, as climate model simulations indicate that each external forcing produces a different characteristic vertical and zonal pattern of temperature response (Hansen et al., 2005b; Hegerl et al., 2007b; Penner et al., 2007; Yoshimori and Broccoli, 2008). GHG forcing is expected to warm the troposphere and cool the stratosphere. Stratospheric ozone depletion cools the stratosphere, with the cooling being most pronounced in the polar regions. Its effect on tropospheric temperatures is small, which is consistent with a small estimated RF of stratospheric ozone changes (SPARC CCMVal, 2010; McLandress et al., 2012). Tropospheric ozone increase, on the other hand, causes tropospheric warming. Reflective aerosols like sulphate cool the troposphere while absorbing aerosols like BC have a warming effect. Free atmosphere temperatures are also affected by natural forcings: solar irradiance increases cause a general warming of the atmosphere and volcanic aerosol ejected into the stratosphere causes tropospheric cooling and stratospheric warming (Hegerl et al., 2007b).

10.3.1.2.1 Tropospheric temperature change

Chapter 2 concludes that it is *virtually certain* that globally the troposphere has warmed since the mid-twentieth century with only *medium* (NH extratropics) to *low confidence* (tropics and SH extratropics) in the rate and vertical structure of these changes. During the satellite era CMIP3 and CMIP5 models tend to warm faster than observations specifically in the tropics (McKitrick et al., 2010; Fu et al., 2011; Po-Chedley and Fu, 2012; Santer et al., 2013); however, because of the large uncertainties in observed tropical temperature trends (Section 2.4.4; Seidel et al. (2012); Figures 2.26 and Figure 2.27) there is only *low confidence* in this assessment (Section 9.4.1.4.2). Outside the tropics, and over the period of the radiosonde record beginning in 1961, the discrepancy between simulated and observed trends is smaller (Thorne et al., 2011; Lott et al., 2013; Santer et al., 2013). Specifically there is better agreement between observed trends and CMIP5 model trends for the NH extratropics (Lott et al., 2013). Factors other than observational uncertainties that contribute to inconsistencies between observed and simulated free troposphere warming include specific manifestation of natural variability in the observed coupled atmosphere–ocean system, forcing errors incorporated in the historical simulations and model response errors (Santer et al., 2013).

Utilizing a subset of CMIP5 models with single forcing experiments extending until 2010, Lott et al. (2013) detect influences of both human induced GHG increase and other anthropogenic forcings (e.g., ozone and aerosols) in the spatio-temporal changes in tropospheric temperatures from 1961 to 2010 estimated from radiosonde observations. Figure 10.8 illustrates that a subsample of CMIP5 models (see Supplementary Material for model selection) forced with both anthropogenic and natural climate drivers (red profiles) exhibit trends that are consistent with radiosonde records in the troposphere up to about 300 hPa, albeit with a tendency for this subset of models to warm more than the observations. This finding is seen in near-globally averaged data (where there is sufficient observational coverage to make a meaningful comparison: 60°S to 60°N) (right panel), as well as in latitudinal bands of the SH extratropics (Figure 10.8, first panel), tropics (Figure 10.8, second panel) and the NH extratropics (Figure 10.8, third panel). Figure 10.8 also illustrates that it is *very unlikely* that natural forcings alone could have caused the observed warming of tropospheric temperatures (blue profiles). The ensembles with both anthropogenic and natural forcings (red) and with GHG forcings only (green) are not clearly separated. This could be due to cancellation of the effects of increases in reflecting aerosols, which cool the troposphere, and absorbing aerosol (Penner et al., 2007) and tropospheric ozone, which both warm the troposphere. Above 300 hPa the three radiosonde data sets exhibit a larger spread as a result of larger uncertainties in the observational record (Thorne et al., 2011; Section 2.4.4). In this region of the upper troposphere simulated CMIP5 temperature trends tend to be more positive than observed trends (Figure 10.8). Further, an assessment of causes of observed trends in the upper troposphere is less confident than an assessment of overall atmospheric temperature changes because of observational uncertainties and potential remain-

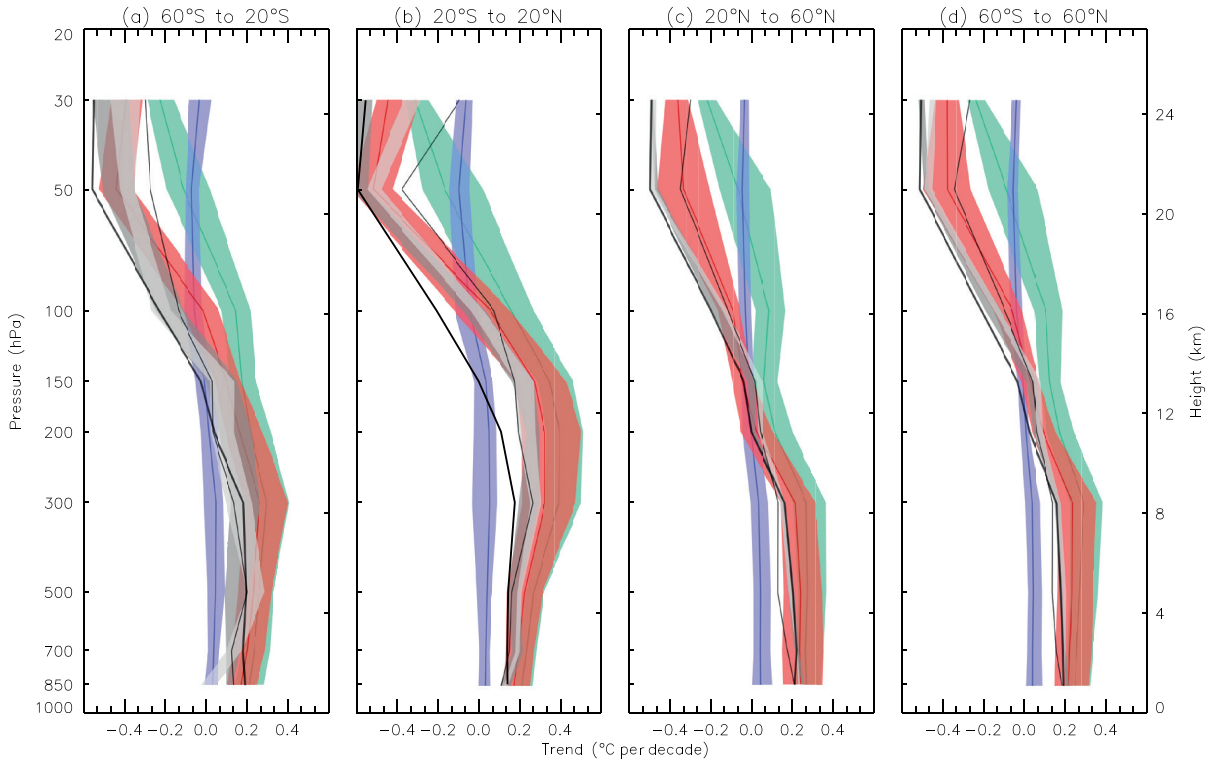

Figure 10.8 | Observed and simulated zonal mean temperatures trends from 1961 to 2010 for CMIP5 simulations containing both anthropogenic and natural forcings (red), natural forcings only (blue) and greenhouse gas forcing only (green) where the 5 to 95th percentile ranges of the ensembles are shown. Three radiosonde observations are shown (thick black line: Hadley Centre Atmospheric Temperature data set 2 (HadAT2), thin black line: RAdiosone OBservation COrrection using REanalyses 1.5 (RAOBCORE 1.5), dark grey band: Radiosonde Innovation Composite Homogenization (RICH)-obs 1.5 ensemble and light grey: RICH- τ 1.5 ensemble. (After Lott et al., 2013.)

ing systematic biases in observational data sets in this region (Thorne et al., 2011; Haimberger et al., 2012). An analysis of contributions of natural and anthropogenic forcings to more recent trends from 1979 to 2010 (Supplementary Material, Figure S.A.1) is less robust because of increased uncertainty in observed trends (consistent with Seidel et al. (2012)) as well as decreased capability to separate between individual forcings ensembles.

One approach to identify a climate change signal in a time series is the analysis of the ratio between the amplitude of the observed signal of change divided by the magnitude of internal variability, in other words the S/N ratio of the data record. The S/N ratio represents the result of a non-optimal fingerprint analysis (in contrast to optimal fingerprint analyses where model-simulated responses and observations are normalized by internal variability to improve the S/N ratio (see Section 10.2.3). For changes in the lower stratospheric temperature between 1979 and 2011, S/N ratios vary from 26 to 36, depending on the choice of observational data set. In the lower troposphere, the fingerprint strength in observations is smaller, but S/N ratios are still significant at the 1% level or better, and range from 3 to 8. There is no evidence that these ratios are spuriously inflated by model variability errors. After all global mean signals are removed, model fingerprints remain identifiable in 70% of the tests involving tropospheric temperature changes (Santer et al., 2013).

Hegerl et al. (2007a) concluded that increasing GHGs are the main cause for warming of the troposphere. This result is supported by a subsample of CMIP5 models that also suggest that the warming effect of well mixed GHGs is partly offset by the combined effects of reflecting aerosols and other forcings. Our understanding has been increased regarding the time scale of detectability of global scale troposphere temperature. Taken together with increased understanding of the uncertainties in observational records of tropospheric temperatures (including residual systematic biases; Section 2.4.4) the assessment remains as it was for AR4 that it is *likely* that anthropogenic forcing has led to a detectable warming of tropospheric temperatures since 1961.

10.3.1.2.2 Stratospheric temperature change

Lower stratospheric temperatures have not evolved uniformly over the period since 1958 when the stratosphere has been observed with sufficient regularity and spatial coverage. A long-term global cooling trend is interrupted by three 2-year warming episodes following large volcanic eruptions (Section 2.4.4). During the satellite period the cooling evolved mainly in two steps occurring in the aftermath of the El Chichón eruption in 1982 and the Mt Pinatubo eruption of 1991, with each cooling transition being followed by a period of relatively steady temperatures (Randel et al., 2009; Seidel et al., 2011). Since the mid-1990s little net change has occurred in lower stratospheric temperatures (Section 2.4.4).

Since AR4, progress has been made in simulating the observed evolution of global mean lower stratospheric temperature. On the one hand, this has been achieved by using models with an improved

representation of stratospheric processes (chemistry–climate models and some CMIP5 models). It is found that in these models which have an upper boundary above the stratopause with an altitude of about 50 km (so-called high-top models) and improved stratospheric physics, variability of lower stratosphere climate in general is well simulated (Butchart et al., 2011; Gillett et al., 2011; Charlton-Perez et al., 2013) whereas in so-called low-top models (including models participating in CMIP3) it is generally underestimated (Cordero and Forster, 2006; Charlton-Perez et al., 2013). On the other hand, CMIP5 models all include changes in stratospheric ozone (Eyring et al., 2013) whereas only about half of the models participating in CMIP3 include stratospheric ozone changes (Section 9.4.1.4.5). A comparison of a low-top and high-top version of the HadGEM2 model shows detectable differences in modelled temperature changes, particularly in the lower tropical stratosphere, with the high-top version's simulation of temperature trends in the tropical troposphere in better agreement with radiosondes and reanalyses over 1981–2010 (Mitchell et al., 2013).

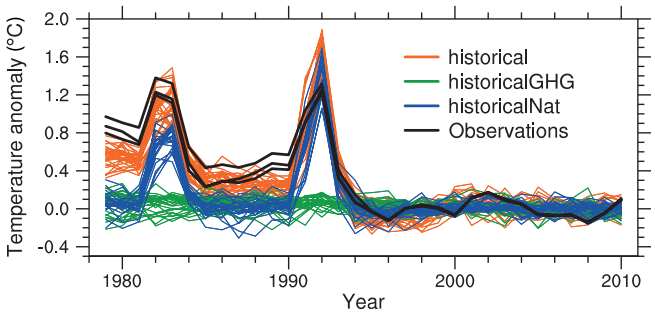

Figure 10.9 | Time series (1979–2010) of observed (black) and simulated global mean (82.5°S to 82.5°N) Microwave Sounding Unit (MSU) lower stratosphere temperature anomalies in a subset of CMIP5 simulations (simulations with both anthropogenic and natural forcings (red), simulations with well-mixed greenhouse gases (green), simulations with natural forcings (blue)). Anomalies are calculated relative to 1996–2010. (Adapted from Ramaswamy et al., 2006.)

CMIP5 models forced with changes in WMGHGs and stratospheric ozone as well as with changes in solar irradiance and volcanic aerosol forcings simulate the evolution of observed global mean lower stratospheric temperatures over the satellite era reasonably well although they tend to underestimate the long-term cooling trend (Charlton-Perez et al., 2013; Santer et al., 2013). Compared with radiosonde data the cooling trend is also underestimated in a subset of CMIP5 simulations over the period 1961–2010 (Figure 10.8) and in CMIP3 models over the 1958–1999 period (Cordero and Forster, 2006). Potential causes for biases in lower stratosphere temperature trends are observational uncertainties (Section 2.4.4) and forcing errors related to prescribed stratospheric aerosol loadings and stratospheric ozone changes affecting the tropical lower stratosphere (Free and Lanzante, 2009; Solomon et al., 2012; Santer et al., 2013).

Since AR4, attribution studies have improved our knowledge of the role of anthropogenic and natural forcings in observed lower stratospheric temperature change. Gillett et al. (2011) use the suite of chemistry climate model simulations carried out as part of the Chemistry Climate Model Validation (CCMVal) activity phase 2 for an attribution study of observed changes in stratospheric zonal mean temperatures. Chemistry–climate models prescribe changes in ozone-depleting substances (ODS) and ozone changes are calculated interactively. Gillett et al. (2011) partition 1979–2005 Microwave Sounding Unit (MSU) lower stratospheric temperature trends into ODS-induced and GHG-induced changes and find that both ODSs and natural forcing contributed to the observed stratospheric cooling in the lower stratosphere with the impact of ODS dominating. The influence of GHGs on stratospheric temperature could not be detected independently of ODSs.

The step-like cooling of the lower stratosphere can only be explained by the combined effects of changes in both anthropogenic and natural factors (Figure 10.9; Eyring et al., 2006; Ramaswamy et al., 2006). Although the anthropogenic factors (ozone depletion and increases in WMGHGs) cause the overall cooling, the natural factors (solar irradiance variations and volcanic aerosols) modulate the evolution of the cooling (Figure 10.9; Ramaswamy et al., 2006; Dall'Amico et al., 2010) with temporal variability of global mean ozone contributing to the step-like temperature evolution (Thompson and Solomon, 2009).

Models disagree with observations for seasonally varying changes in the strength of the Brewer–Dobson circulation in the lower stratosphere (Ray et al., 2010) which has been linked to zonal and seasonal patterns of changes in lower stratospheric temperatures (Thompson and Solomon, 2009; Fu et al., 2010; Lin et al., 2010b; Forster et al., 2011; Free, 2011). One robust feature is the observed cooling in spring over the Antarctic, which is simulated in response to stratospheric ozone depletion in climate models (Young et al., 2012), although this has not been the subject of a formal detection and attribution study.

Since AR4, progress has been made in simulating the response of global mean lower stratosphere temperatures to natural and anthropogenic forcings by improving the representation of climate forcings and utilizing models that include more stratospheric processes. New detection and attribution studies of lower stratospheric temperature changes made since AR4 support an assessment that it is *very likely* that anthropogenic forcing, dominated by stratospheric ozone depletion due to ozone-depleting substances, has led to a detectable cooling of the lower stratosphere since 1979.

10.3.1.2.3 Overall atmospheric temperature change

When temperature trends from the troposphere and stratosphere are analysed together, detection and attribution studies using CMIP5 models show robust detections of the effects of GHGs and other anthropogenic forcings on the distinctive fingerprint of tropospheric warming and stratospheric cooling seen since 1961 in radiosonde data (Lott et al., 2013; Mitchell et al., 2013). Combining the evidence from free atmosphere changes from both troposphere and stratosphere shows an increased confidence in the attribution of free atmosphere temperature changes compared to AR4 owing to improved understanding of stratospheric temperature changes. There is therefore stronger evidence than at the time of AR4 to support the conclusion that it is *very likely* that anthropogenic forcing, particularly GHGs and stratospheric ozone depletion, has led to a detectable observed pattern of tropospheric warming and lower stratospheric cooling since 1961.

Frequently Asked Questions

FAQ 10.1 | Climate Is Always Changing. How Do We Determine the Causes of Observed Changes?

The causes of observed long-term changes in climate (on time scales longer than a decade) are assessed by determining whether the expected 'fingerprints' of different causes of climate change are present in the historical record. These fingerprints are derived from computer model simulations of the different patterns of climate change caused by individual climate forcings. On multi-decade time scales, these forcings include processes such as greenhouse gas increases or changes in solar brightness. By comparing the simulated fingerprint patterns with observed climate changes, we can determine whether observed changes are best explained by those fingerprint patterns, or by natural variability, which occurs without any forcing.

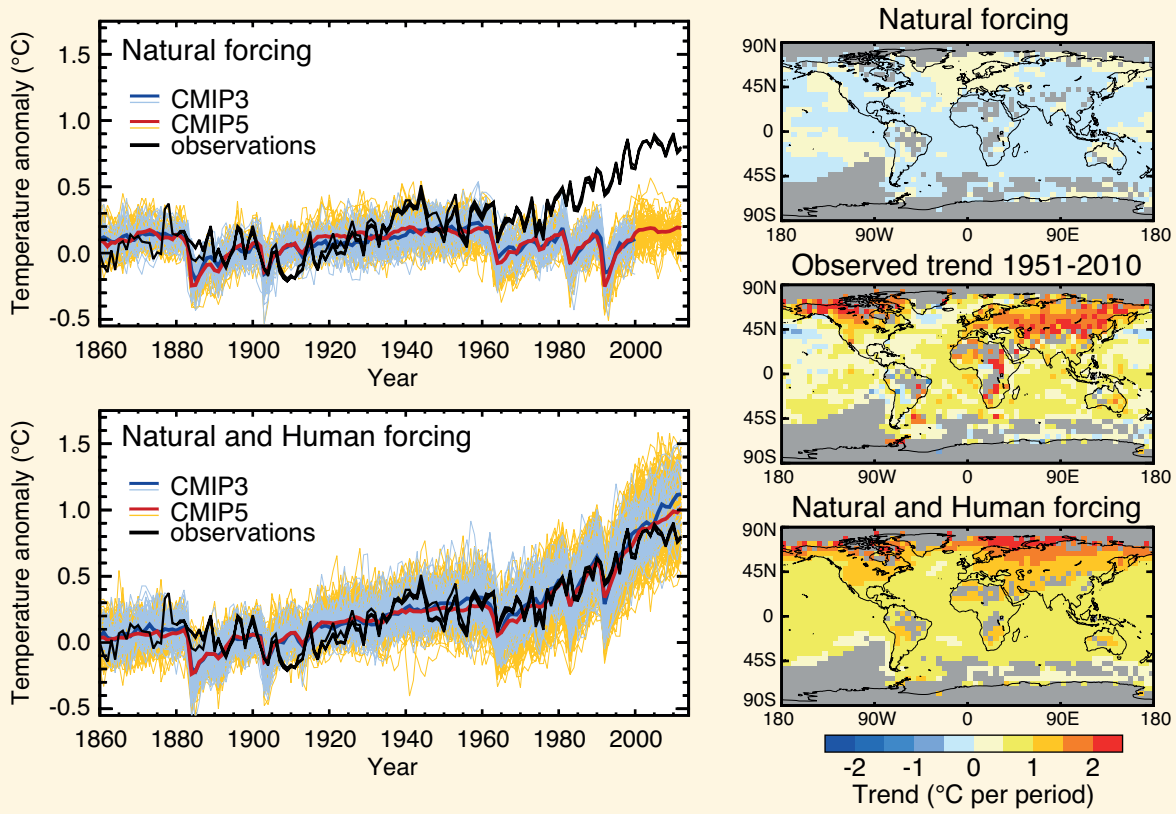
The fingerprint of human-caused greenhouse gas increases is clearly apparent in the pattern of observed 20th century climate change. The observed change cannot be otherwise explained by the fingerprints of natural forcings or natural variability simulated by climate models. Attribution studies therefore support the conclusion that 'it is extremely likely *that human activities have caused more than half of the observed increase in global mean surface temperatures from 1951 to 2010.'*

The Earth's climate is always changing, and that can occur for many reasons. To determine the principal causes of observed changes, we must first ascertain whether an observed change in climate is different from other fluctuations that occur without any forcing at all. Climate variability without forcing—called internal variability—is the consequence of processes within the climate system. Large-scale oceanic variability, such as El Niño-Southern Oscillation (ENSO) fluctuations in the Pacific Ocean, is the dominant source of internal climate variability on decadal to centennial time scales.

Climate change can also result from natural forcings external to the climate system, such as volcanic eruptions, or changes in the brightness of the sun. Forcings such as these are responsible for the huge changes in climate that are clearly documented in the geological record. Human-caused forcings include greenhouse gas emissions or atmospheric particulate pollution. Any of these forcings, natural or human caused, could affect internal variability as well as causing a change in average climate. Attribution studies attempt to determine the causes of a detected change in observed climate. Over the past century we know that global average temperature has increased, so if the observed change is forced then the principal forcing must be one that causes warming, not cooling.

Formal climate change attribution studies are carried out using controlled experiments with climate models. The model-simulated responses to specific climate forcings are often called the fingerprints of those forcings. A climate model must reliably simulate the fingerprint patterns associated with individual forcings, as well as the patterns of unforced internal variability, in order to yield a meaningful climate change attribution assessment. No model can perfectly reproduce all features of climate, but many detailed studies indicate that simulations using current models are indeed sufficiently reliable to carry out attribution assessments.

FAQ 10.1, Figure 1 illustrates part of a fingerprint assessment of global temperature change at the surface during the late 20th century. The observed change in the latter half of the 20th century, shown by the black time series in the left panels, is larger than expected from just internal variability. Simulations driven only by natural forcings (yellow and blue lines in the upper left panel) fail to reproduce late 20th century global warming at the surface with a spatial pattern of change (upper right) completely different from the observed pattern of change (middle right). Simulations including both natural and human-caused forcings provide a much better representation of the time rate of change (lower left) and spatial pattern (lower right) of observed surface temperature change.



Both panels on the left show that computer models reproduce the naturally forced surface cooling observed for a year or two after major volcanic eruptions, such as occurred in 1982 and 1991. Natural forcing simulations capture the short-lived temperature changes following eruptions, but only the natural + human caused forcing simulations simulate the longer-lived warming trend.

A more complete attribution assessment would examine temperature above the surface, and possibly other climate variables, in addition to the surface temperature results shown in FAQ 10.1, Figure 1. The fingerprint patterns associated with individual forcings become easier to distinguish when more variables are considered in the assessment.

(continued on next page)

FAQ 10.1 (continued)

Overall, FAQ 10.1, Figure 1 shows that the pattern of observed temperature change is significantly different than the pattern of response to natural forcings alone. The simulated response to all forcings, including human-caused forcings, provides a good match to the observed changes at the surface. We cannot correctly simulate recent observed climate change without including the response to human-caused forcings, including greenhouse gases, stratospheric ozone, and aerosols. Natural causes of change are still at work in the climate system, but recent trends in temperature are largely attributable to human-caused forcing.

FAQ 10.1, Figure 1 | (Left) Time series of global and annual-averaged surface temperature change from 1860 to 2010. The top left panel shows results from two ensemble of climate models driven with just natural forcings, shown as thin blue and yellow lines; ensemble average temperature changes are thick blue and red lines. Three different observed estimates are shown as black lines. The lower left panel shows simulations by the same models, but driven with both natural forcing and human-induced changes in greenhouse gases and aerosols. (Right) Spatial patterns of local surface temperature trends from 1951 to 2010. The upper panel shows the pattern of trends from a large ensemble of Coupled Model Intercomparison Project Phase 5 (CMIP5) simulations driven with just natural forcings. The bottom panel shows trends from a corresponding ensemble of simulations driven with natural + human forcings. The middle panel shows the pattern of observed trends from the Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4) during this period.

10.3.2 Water Cycle

Detection and attribution studies of anthropogenic change in hydrologic variables are challenged by the length and quality of observed data sets, and by the difficulty in simulating hydrologic variables in dynamical models. AR4 cautiously noted that the observed increase in atmospheric water vapour over oceans was consistent with warming of SSTs attributed to anthropogenic influence, and that observed changes in the latitudinal distribution of precipitation, and increased incidence of drought, were suggestive of a possible human influence. Many of the published studies cited in AR4, and some of the studies cited in this section, use less formal detection and attribution criteria than are often used for assessments of temperature change, owing to difficulties defining large-scale fingerprint patterns of hydrologic change in models and isolating those fingerprints in data. For example, correlations between observed hydrologic changes and the patterns of change in models forced by increasing GHGs can provide suggestive evidence towards attribution of change.

Since the publication of AR4, *in situ* hydrologic data sets have been reanalysed with more stringent quality control. Satellite-derived data records of worldwide water vapour and precipitation variations have

lengthened. Formal detection and attribution studies have been carried out with newer models that potentially offer better simulations of natural variability. Reviews of detection and attribution of trends in various components of the water cycle have been published by Stott et al. (2010) and Trenberth (2011b).

10.3.2.1 Changes in Atmospheric Water Vapour

In situ surface humidity measurements have been reprocessed since AR4 to create new gridded analyses for climatic research, as discussed in Chapter 2. The HadCRUH Surface Humidity data set (Willett et al., 2008) indicates significant increases in surface specific humidity between 1973 and 2003 averaged over the globe, the tropics, and the NH, with consistently larger trends in the tropics and in the NH during summer, and negative or non significant trends in relative humidity. These results are consistent with the hypothesis that the distribution of relative humidity should remain roughly constant under climate change (see Section 2.5). Simulations of the response to historical anthropogenic and natural forcings robustly generate an increase in atmospheric humidity consistent with observations (Santer et al., 2007; Willett et al., 2007; Figure 9.9). A recent cessation of the upward trend in specific humidity is observed over multiple continental areas in HadCRUH and is also found in the European Centre for Medium range Weather Forecast (ECMWF) interim reanalysis of the global atmosphere and surface conditions (ERA-Interim; Simmons et al. 2010). This change in the specific humidity trend is temporally correlated with a levelling off of global ocean temperatures following the 1997–1998 El Niño event (Simmons et al., 2010).

The anthropogenic water vapour fingerprint simulated by an ensemble of 22 climate models has been identified in lower tropospheric moisture content estimates derived from Special Sensor Microwave/Imager (SSM/I) data covering the period 1988–2006 (Santer et al., 2007). Santer et al. (2009) find that detection of an anthropogenic response in column water vapour is insensitive to the set of models used. They rank models based on their ability to simulate the observed mean total column water vapour, and its annual cycle and variability associated with ENSO. They report no appreciable differences between the fingerprints or detection results derived from the best or worst performing models, and so conclude that attribution of water vapour changes to anthropogenic forcing is not sensitive to the choice of models used for the assessment.

In summary, an anthropogenic contribution to increases in specific humidity at and near the Earth's surface is found with *medium confidence*. Evidence of a recent levelling off of the long-term surface atmospheric moistening trend over land needs to be better understood and simulated as a prerequisite to increased confidence in attribution studies of water vapour changes. Length and quality of observational humidity data sets, especially above the surface, continue to limit detection and attribution studies of atmospheric water vapour.

10.3.2.2 Changes in Precipitation

Analysis of CMIP5 model simulations yields clear global and regional scale changes associated with anthropogenic forcing (e.g., Scheff and Frierson, 2012a, 2012b), with patterns broadly similar to those identified from CMIP3 models (e.g., Polson et al., 2013). The AR4 concluded that 'the latitudinal pattern of change in land precipitation and observed increases in heavy precipitation over the 20th century appear to be consistent with the anticipated response to anthropogenic forcing'. Detection and attribution of regional precipitation changes generally focuses on continental areas using *in situ* data because observational coverage over oceans is limited to a few island stations (Arkin et al., 2010; Liu et al., 2012; Noake et al., 2012) , although model-data comparisons over continents also illustrate large observational uncertainties (Tapiador, 2010; Noake et al., 2012; Balan Sarojini et al., 2012; Polson et al., 2013). Available satellite data sets that could supplement oceanic studies are short and their long-term homogeneity is still unclear (Chapter 2); hence they have not yet been used for detection and attribution of changes. Continuing uncertainties in climate model simulations of precipitation make quantitative model/data comparisons difficult (e.g., Stephens et al., 2010), which also limits confidence in detection and attribution. Furthermore, sparse observational coverage of precipitation across much of the planet makes the fingerprint of precipitation change challenging to isolate in observational records (Balan Sarojini et al., 2012; Wan et al., 2013).

Considering just land regions with sufficient observations, the largest signal of differences between models with and without anthropogenic forcings is in the high latitudes of the NH, where increases in precipitation are a robust feature of climate model simulations (Scheff and Frierson, 2012a, 2012b). Such increases have been observed (Figure 10.10) in several different observational data sets (Min et al., 2008a; Noake et al., 2012; Polson et al., 2013), although high-latitude trends vary between data sets and with coverage (e.g., Polson et al., 2013).

Attribution of zonally averaged precipitation trends has been attempted using different observational products and ensembles of forced simulations from both the CMIP3 and CMIP5 archives, for annual-averaged (Zhang et al., 2007; Min et al., 2008a) and season-specific (Noake et al., 2012; Polson et al., 2013) results (Figure 10.11). Zhang et al. (2007) identify the fingerprint of anthropogenic changes in observed annual zonal mean precipitation averaged over the periods 1925–1999 and 1950–1999, and separate the anthropogenic fingerprint from the influence of natural forcing. The fingerprint of external forcing is also detected in seasonal means for boreal spring in all data sets assessed by Noake et al. (2012), and in all but one data set assessed by Polson et al. (2013) (Figure 10.11), and in boreal winter in all but one data set (Noake et al., 2012), over the period 1951–1999 and to 2005. The fingerprint features increasing high-latitude precipitation, and decreasing precipitation trends in parts of the tropics that are reasonably robustly observed in all four data sets considered albeit with large observational uncertainties north of 60°N (Figure 10.11). Detection of seasonal-average precipitation change is less convincing for June, July, August (JJA) and September, October, November (SON) and results vary with observation data set (Noake et al., 2012; Polson et al., 2013). Although Zhang et al. (2007) detect anthropogenic changes even if a separate fingerprint for natural forcings is considered, Polson et al. (2013) find that this result is sensitive to the data set used and that the fingerprints can be separated robustly only for the data set most closely constrained by station data. The analysis also finds that model simulated precipitation variability is smaller than observed variability in the tropics (Zhang et al., 2007;

Polson et al., 2013) which is addressed by increasing the estimate of variance from models (Figure 10.11).

Another detection and attribution study focussed on precipitation in the NH high latitudes and found an attributable human influence (Min et al., 2008a). Both Min et al. (2008a) and Zhang et al. (2007) find that the observed changes are significantly larger than the model simulated changes. However, Noake et al. (2012) and Polson et al. (2013) find that the difference between models and observations decreases if changes are expressed as a percentage of climatological precipitation and that the observed and simulated changes are largely consistent between CMIP5 models and observations given data uncertainty. Use of additional data sets illustrates remaining observational uncertainty in high latitudes of the NH (Figure 10.11). Regional-scale attribution of precipitation change is still problematic although regional climate models have yielded simulations consistent with observed wintertime changes for northern Europe (Bhend and von Storch, 2008; Tapiador, 2010).

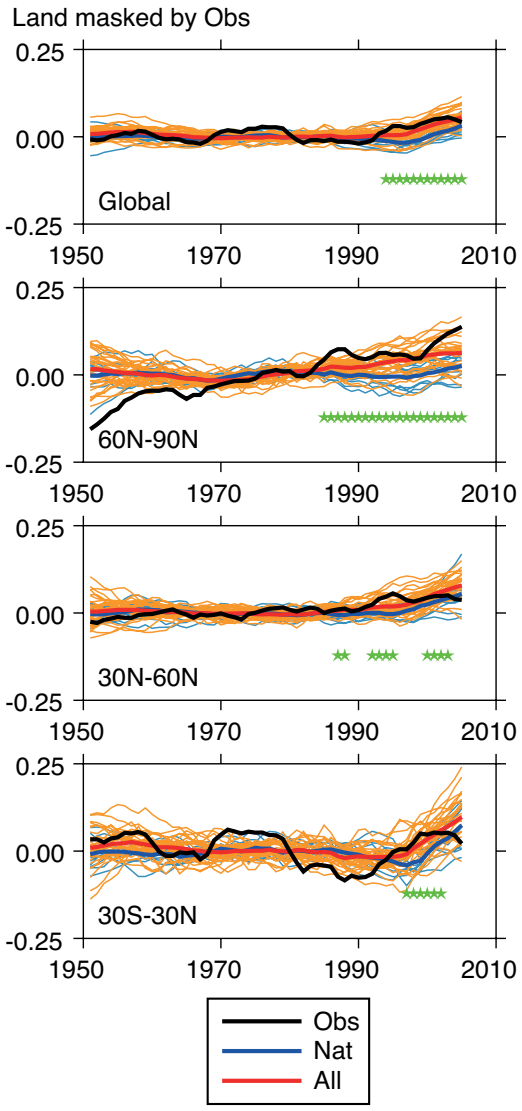


Figure 10.10 | Global and zonal average changes in annual mean precipitation (mm day^{-1}) over areas of land where there are observations, expressed relative to the baseline period of 1961–1990, simulated by CMIP5 models forced with both anthropogenic and natural forcings (red lines) and natural forcings only (blue lines) for the global mean and for three latitude bands. Multi-model means are shown in thick solid lines. Observations (gridded values derived from Global Historical Climatology Network station data, updated from Zhang et al. (2007) are shown as a black solid line. An 11-year smoothing is applied to both simulations and observations. Green stars show statistically significant changes at 5% level (p value <0.05) between the ensemble of runs with both anthropogenic and natural forcings (red lines) and the ensemble of runs with just natural forcings (blue lines) using a two-sample two-tailed t-test for the last 30 years of the time series. (From Balan Sarojini et al., 2012.) Results for the Climate Research Unit (CRU) TS3.1 data set are shown in Figure 10.A.2.

Precipitation change over ocean has been attributed to human influence by Fyfe et al. (2012) for the high-latitude SH in austral summer, where zonally averaged precipitation has declined around 45°S and increased around 60°S since 1957, consistent with CMIP5 historical simulations, with the magnitude of the half-century trend outside the range of simulated natural variability. Confidence in this attribution result, despite limitations in precipitation observations, is enhanced by its consistency with trends in large-scale sea level pressure data (see Section 10.3.3).

In summary, there is *medium confidence* that human influence has contributed to large-scale changes in precipitation patterns over land. The expected anthropogenic fingerprints of change in zonal mean precipitation—reductions in low latitudes and increases in NH mid to high latitudes—have been detected in annual and some seasonal data. Observational uncertainties including limited global coverage and large natural variability, in addition to challenges in precipitation modeling, limit confidence in assessment of climatic changes in precipitation.

10.3.2.3 Changes in Surface Hydrologic Variables

This subsection assesses recent research on detection and attribution of long-term changes in continental surface hydrologic variables, including soil moisture, evapotranspiration and streamflow. Streamflows are often subject to large non-climatic human influence, such as diversions and land use changes, that must be accounted for in order to attribute detected hydrologic changes to climate change. Cryospheric aspects of surface hydrology are discussed in Section 10.5; extremes in surface hydrology (such as drought) and precipitation are covered in Section 10.6.1. The variables discussed here are subject to large modeling uncertainties (Chapter 9) and observational challenges (Chapter 2), which in combination place severe limits on climate change detection and attribution.

Direct observational records of soil moisture and surface fluxes tend to be sparse and/or short, thus limiting recent assessments of change in these variables (Jung et al., 2010). Assimilated land surface data sets and new satellite observations (Chapter 2) are promising tools, but assessment of past and future climate change of these variables (Hoekema and Sridhar, 2011) is still generally carried out on derived quantities such as the Palmer Drought Severity Index, as discussed more fully in Section 10.6.1. Recent observations (Jung et al., 2010) show regional trends towards drier soils. An optimal detection analysis of reconstructed evapotranspiration identifies the effects of anthropogenic forcing on evapotranspiration, with the Centre National de Recherches Météorologiques (CNRM)-CM5 model simulating changes consistent with those estimated to have occurred (Douville et al., 2013).

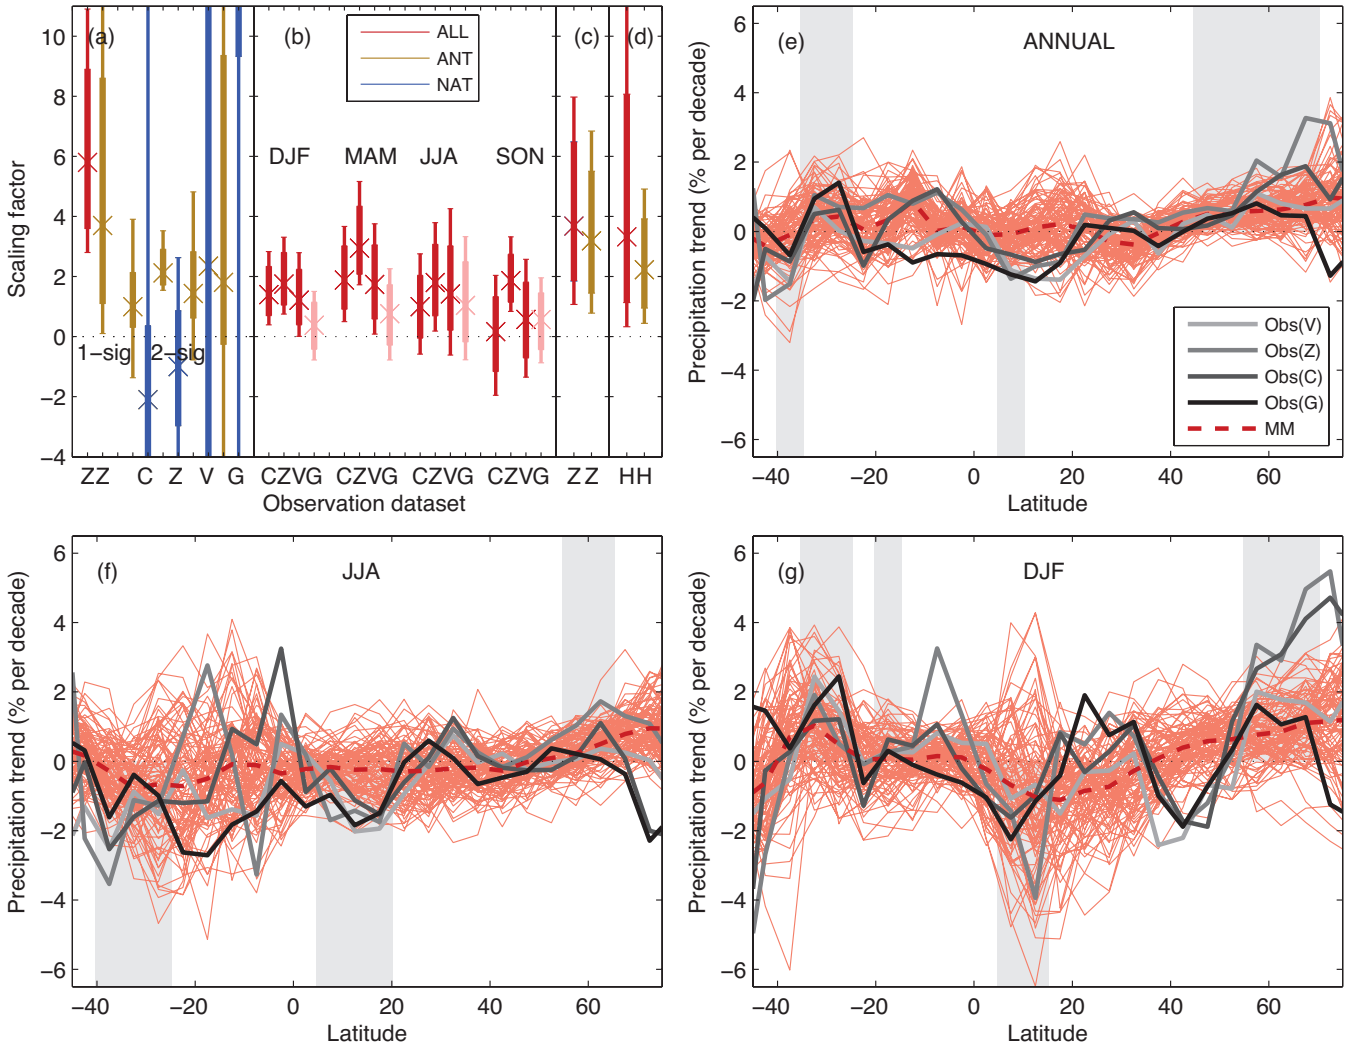

Figure 10.11 | Detection and attribution results for zonal land precipitation trends in the second half of the 20th century. (Top left) Scaling factors for precipitation changes. (Top right and bottom) Zonally averaged precipitation changes over continents from models and observations. (a) Crosses show the best-guess scaling factor derived from multi-model means. Thick bars show the 5 to 95% uncertainty range derived from model-simulated variability, and thin bars show the uncertainty range if doubling the multi-model variance. Red bars indicate scaling factors for the estimated response to all forcings, blue bars for natural-only forcing and brown bars for anthropogenic-only forcing. Labels on the *x*-axis identify results from four different observational data sets (Z is Zhang et al. (2007), C is Climate Research Unit (CRU), V is Variability Analyses of Surface Climate Observations (VASClimO), G is Global Precipitation Climatology Centre (GPCC), H is Hadley Centre gridded data set of temperature and precipitation extremes (HadEX)). (a) Detection and attribution results for annual averages, both single fingerprint ("1-sig"; 1950–1999) and two fingerprint results ("2-sig"; Z, C, G (1951–2005), V (1952–2000)). (b) Scaling factors resulting from single-fingerprint analyses for seasonally averaged precipitation (Z, C, G (1951–2005), V (1952–2000); the latter in pink as not designed for long-term homogeneity) for four different seasons. (c) Scaling factors for spatial pattern of Arctic precipitation trends (1951–1999). (d) Scaling factors for changes in large-scale intense precipitation (1951–1999). (e) Thick solid lines show observed zonally and annually averaged trends (% per decade) for four different observed data sets. Corresponding results from individual simulations from 33 different climate models are shown as thin solid lines, with the multimodel mean shown as a red dashed line. Model results are masked to match the spatial and temporal coverage of the GPCC data set (denoted G in the seasonal scaling factor panel). Grey shading indicates latitude bands within which >75% of simulations yield positive or negative trends. (f, g) Like (e) but showing zonally averaged precipitation changes for (f) June, July, August (JJA) and (g) December, January, February (DJF) seasons. Scaling factors (c) and (d) adapted from Min et al. (2008a) and Min et al. (2011), respectively; other results adapted from Zhang et al. (2007) and Polson et al. (2013).

Trends towards earlier timing of snowmelt-driven streamflows in western North America since 1950 have been demonstrated to be different from natural variability (Hidalgo et al., 2009). Similarly, internal variability associated with natural decade-scale fluctuations could not account for recent observed declines of northern Rocky Mountain streamflow (St Jacques et al., 2010). Statistical analyses of streamflows demonstrate regionally varying changes that are consistent with changes expected from increasing temperature, in Scandinavia (Wilson et al., 2010), Europe (Stahl et al., 2010) and the USA (Krakauer and Fung, 2008; Wang and Hejazi, 2011). Observed increases in Arctic river discharge, which could be a good integrator for monitoring changes in precipitation in high latitudes, are found to be explainable only if model simulations include anthropogenic forcings (Min et al., 2008a).

Barnett et al. (2008) analysed changes in the surface hydrology of the western USA, considering snow pack (measured as snow water equivalent), the seasonal timing of streamflow in major rivers, and average January to March daily minimum temperature over the region, the two hydrological variables they studied being closely related to temperature. Observed changes were compared with the output of a

regional hydrologic model forced by the Parallel Climate Model (PCM) and Model for Interdisciplinary Research On Climate (MIROC) climate models. They derived a fingerprint of anthropogenic changes from the two climate models and found that the observations, when projected onto the fingerprint of anthropogenic changes, show a positive signal strength consistent with the model simulations that falls outside the range expected from internal variability as estimated from 1600 years of downscaled climate model data. They conclude that there is a detectable and attributable anthropogenic signature on the hydrology of this region.

In summary, there is *medium confidence* that human influence on climate has affected stream flow and evapotranspiration in limited regions of middle and high latitudes of the NH. Detection and attribution studies have been applied only to limited regions and using a few models. Observational uncertainties are large and in the case of evapotranspiration depend on reconstructions using land surface models.

10.3.3 Atmospheric Circulation and Patterns of Variability

The atmospheric circulation is driven by various processes including the uneven heating of the Earth's surface by solar radiation, land–sea contrast and orography. The circulation transports heat from warm to cold regions and thereby acts to reduce temperature contrasts. Thus, changes in circulation and in patterns of variability are of critical importance for the climate system, influencing regional climate and regional climate variability. Any such changes are important for local climate change because they could act to reinforce or counteract the effects of external forcings on climate in a particular region. Observed changes in atmospheric circulation and patterns of variability are assessed in Section 2.7.5. Although new and improved data sets are now available, changes in patterns of variability remain difficult to detect because of large variability on interannual to decadal time scales (Section 2.7).

Since AR4, progress has been made in understanding the causes of changes in circulation-related climate phenomena and modes of variability such as the width of the tropical circulation, and the Southern Annular Mode (SAM). For other climate phenomena, such as ENSO, Indian Ocean Dipole (IOD), Pacific Decadal Oscillation (PDO), and monsoons, there are large observational and modelling uncertainties (see Section 9.5 and Chapter 14), and there is *low confidence* that changes in these phenomena, if observed, can be attributed to human-induced influence.

10.3.3.1 Tropical Circulation

Various indicators of the width of the tropical belt based on independent data sets suggest that the tropical belt as a whole has widened since 1979; however, the magnitude of this change is very uncertain (Fu et al., 2006; Hudson et al., 2006; Hu and Fu, 2007; Seidel and Randel, 2007; Seidel et al., 2008; Lu et al., 2009; Fu and Lin, 2011; Hu et al., 2011; Davis and Rosenlof, 2012; Lucas et al., 2012; Wilcox et al., 2012; Nguyen et al., 2013) (Section 2.7.5). CMIP3 and CMIP5 simulations suggest that anthropogenic forcings have contributed to the observed widening of the tropical belt since 1979 (Johanson and Fu, 2009; Hu et al., 2013). On average the poleward expansion of the Hadley circulation and other indicators of the width of the tropical belt is greater than determined from CMIP3 and CMIP5 simulations (Seidel et al., 2008; Johanson and Fu, 2009; Hu et al., 2013; Figure 10.12). The causes as to why models underestimate the observed poleward expansion of the tropical belt are not fully understood. Potential factors are lack of understanding of the magnitude of natural variability as well as changes in observing systems that also affect reanalysis products (Thorne and Vose, 2010; Lucas et al., 2012; Box 2.3).

Climate model simulations suggest that Antarctic ozone depletion is a major factor in causing poleward expansion of the southern Hadley cell during austral summer over the last three to five decades with GHGs also playing a role (Son et al., 2008, 2009, 2010; McLandress et al., 2011; Polvani et al., 2011; Hu et al., 2013). In reanalysis data a detectable signal of ozone forcing is separable from other external forcing including GHGs when utilizing both CMIP5 and CMIP3 simulations combined (Min and Son, 2013). An analysis of CMIP3 simulations suggests that BC aerosols and tropospheric ozone were the main drivers of the observed poleward expansion of the northern Hadley cell in boreal summer (Allen et al., 2012). It is found that global greenhouse warming causes increase in static stability, such that the onset of baroclinicity is shifted poleward, leading to poleward expansion of the Hadley circulation (Frierson, 2006; Frierson et al., 2007; Hu and Fu, 2007; Lu et al., 2007, 2008). Tropical SST increase may also contribute to a widening of the Hadley circulation (Hu et al., 2011; Staten et al., 2012). Althoughe some Atmospheric General Circulation Model (AGCM) simulations forced by observed time-varying SSTs yield a widening by about 1° in latitude over 1979–2002 (Hu et al., 2011), other simulations suggest that SST changes have little effect on the tropical expansion when based on the tropopause metric of the tropical width (Lu et al., 2009). However, it is found that the tropopause metric is not

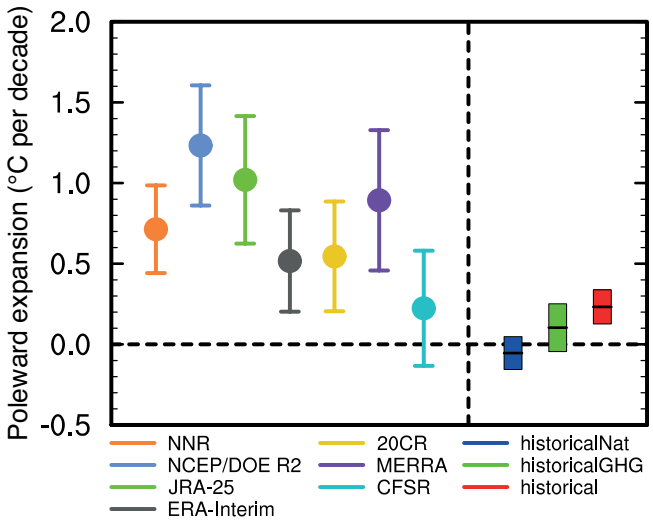

Figure 10.12 | December to February mean change of southern border of the Hadley circulation. Unit is degree in latitude per decade. Reanalysis data sets (see also Box 2.3) are marked with different colours. Trends are all calculated over the period of 1979–2005. The terms historicalNAT, historicalGHG, and historical denote CMIP5 simulations with natural forcing, with greenhouse gas forcing and with both anthropogenic and natural forcings, respectively. For each reanalysis data set, the error bars indicate the 95% confidence level of the standard *t*-test. For CMIP5 simulations, trends are first calculated for each model, and all ensemble members of simulations are used. Then, trends are averaged for multi-model ensembles. Trend uncertainty is estimated from multi-model ensembles, as twice the standard error. (Updated from Hu et al., 2013.)

very reliable because of the use of arbitrary thresholds (Birner, 2010; Davis and Rosenlof, 2012).

In summary, there are multiple lines of evidence that the Hadley cell and the tropical belt as a whole have widened since at least 1979; however, the magnitude of the widening is very uncertain. Based on modelling studies there is *medium confidence* that stratospheric ozone depletion has contributed to the observed poleward shift of the southern Hadley cell border during austral summer, with GHGs also playing a role. The contribution of internal climate variability to the observed poleward expansion of the Hadley circulation remains very uncertain.

10.3.3.2 Northern Annular Mode/North Atlantic Oscillation

The NAO, which exhibited a positive trend from the 1960s to the 1990s, has since exhibited lower values, with exceptionally low anomalies in the winters of 2009/2010 and 2010/2011 (Section 2.7.8). This means that the positive trend in the NAO discussed in the AR4 has considerably weakened when evaluated up to 2011. Similar results apply to the closely related Northern Annular Mode (NAM), with its upward trend over the past 60 years in the 20th Century Reanalysis (Compo et al., 2011) and in Hadley Centre Sea Level Pressure data set 2r (HadSLP2r; Allan and Ansell, 2006) not being significant compared to internal variability (Figure 10.13). An analysis of CMIP5 models shows that they simulate positive trends in NAM in the DJF season over this period, albeit not as large as those observed which are still within the range of natural internal variability (Figure 10.13).

Other work (Woollings, 2008) demonstrates that while the NAM is largely barotropic in structure, the simulated response to anthropogenic forcing has a strong baroclinic component, with an opposite geopotential height trends in the mid-troposphere compared to the surface in many models. Thus while the circulation response to anthropogenic forcing may project onto the NAM, it is not entirely captured by the NAM index.

Consistent with previous findings (Hegerl et al., 2007b), Gillett and Fyfe (2013) find that GHGs tend to drive a positive NAM response in the CMIP5 models. Recent modelling work also indicates that ozone changes drive a small positive NAM response in spring (Morgenstern et al., 2010; Gillett and Fyfe, 2013).

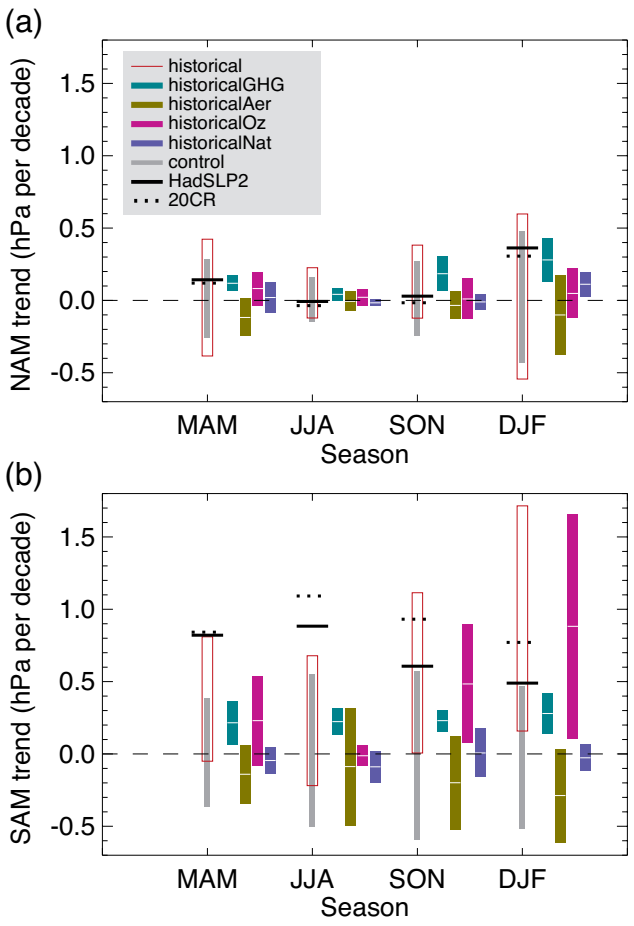

Figure 10.13 | Simulated and observed 1951–2011 trends in the Northern Annular Mode (NAM) index (a) and Southern Annular Mode (SAM) index (b) by season. The NAM is a Li and Wang (2003) index based on the difference between zonal mean seal level pressure (SLP) at 35°N and 65°N. and the, and the SAM index is a difference between zonal mean SLP at 40°S and 65°S (Gong and Wang, 1999). Both indices are defined without normalization, so that the magnitudes of simulated and observed trends can be compared. Black lines show observed trends from the HadSLP2r data set (Allan and Ansell, 2006) (solid), and the 20th Century Reanalysis (Compo et al., 2011) (dotted). Grey bars and red boxes show 5 to 95% ranges of trends in CMIP5 control and historical simulations respectively. Ensemble mean trends and their 5 to 95% uncertainties are shown for the response to greenhouse gases (light green), aerosols (dark green), ozone (magenta) and natural (blue) forcing changes, based on CMIP5 individual forcing simulations. (Adapted from Gillett and Fyfe, 2013.)

10.3.3.3 Southern Annular Mode

The Southern Annular Mode (SAM) index has remained mainly positive since the publication of the AR4, although it has not been as strongly positive as in the late 1990s. Nonetheless, an index of the SAM shows a significant positive trend in most seasons and data sets over the 1951–2011 period (Figure 10.13; Table 2.14). Recent modelling studies confirm earlier findings that the increase in GHG concentrations tends to lead to a strengthening and poleward shift of the SH eddy-driven polar jet (Karpechko et al., 2008; Son et al., 2008, 2010; Sigmond et al., 2011; Staten et al., 2012; Swart and Fyfe, 2012; Eyring et al., 2013; Gillett and Fyfe, 2013) which projects onto the positive phase of the SAM. Stratospheric ozone depletion also induces a strengthening and poleward shift of the polar jet in models, with the largest response in austral summer (Karpechko et al., 2008; Son et al., 2008, 2010; McLandress et al., 2011; Polvani et al., 2011; Sigmond et al., 2011; Gillett and Fyfe, 2013). Sigmond et al. (2011) find approximately equal contributions to simulated annual mean SAM trends from GHGs and stratospheric ozone depletion up to the present. Fogt et al. (2009) demonstrate that observed SAM trends over the period 1957–2005 are positive in all seasons, but only statistically significant in DJF and March, April, May (MAM), based on simulated internal variability. Roscoe and Haigh (2007) apply a regression-based approach and find that stratospheric ozone changes are the primary driver of observed trends in the SAM. Observed trends are also consistent with CMIP3 simulations including stratospheric ozone changes in all seasons, though in MAM observed trends are roughly twice as large as those simulated (Miller et al., 2006). Broadly consistent results are found when comparing observed trends and CMIP5 simulations (Figure 10.13), with a station-based SAM index showing a significant positive trend in MAM, JJA and DJF, compared

to simulated internal variability over the 1951–2010 period. Fogt et al. (2009) find that the largest forced response has likely occurred in DJF, the season in which stratospheric ozone depletion has been the dominant contributor to the observed trends.

Taking these findings together, it is *likely* that the positive trend in the SAM seen in austral summer since the mid-20th century is due in part to stratospheric ozone depletion. There is *medium confidence* that GHGs have also played a role.

10.3.3.4 Change in Global Sea Level Pressure Patterns

A number of studies have applied formal detection and attribution studies to global fields of atmospheric SLP finding detection of human influence on global patterns of SLP (Gillett et al., 2003, 2005; Gillett and Stott, 2009). Analysing the contributions of different forcings to observed changes in SLP, Gillett and Stott (2009) find separately detectable influences of anthropogenic and natural forcings in zonal mean seasonal mean SLP, strengthening evidence for a human influence on SLP. Based on the robustness of the evidence from multiple models we conclude that it is *likely* that human influence has altered SLP patterns globally since 1951.

10.4 Changes in Ocean Properties

This section assesses the causes of oceanic changes in the main properties of interest for climate change: ocean heat content, ocean salinity and freshwater fluxes, sea level, oxygen and ocean acidification.

10.4.1 Ocean Temperature and Heat Content

The oceans are a key part of the Earth's energy balance (Boxes 3.1 and 13.1). Observational studies continue to demonstrate that the ocean heat content has increased in the upper layers of the ocean during the second half of the 20th century and early 21st century (Section 3.2; Bindoff et al., 2007), and that this increase is consistent with a net positive radiative imbalance in the climate system. It is of significance that this heat content increase is an order of magnitude larger than the increase in energy content of any other component of the Earth's ocean–atmosphere–cryosphere system and accounts for more than 90% of the Earth's energy increase between 1971 and 2010 (e.g., Boxes 3.1 and 13.1; Bindoff et al., 2007; Church et al., 2011; Hansen et al., 2011).

Despite the evidence for anthropogenic warming of the ocean, the level of confidence in the conclusions of the AR4 report—that the warming of the upper several hundred meters of the ocean during the second half of the 20th century was *likely* to be due to anthropogenic forcing—reflected the level of uncertainties at that time. The major uncertainty was an apparently large decadal variability (warming in the 1970s and cooling in the early 1980s) in the observational estimates that was not simulated by climate models (Hegerl et al., 2007b, see their Table 9.4). The large decadal variability in observations raised concerns about the capacity of climate models to simulate observed variability. There were also lingering concerns about the presence of non-climate–related biases in the observations of ocean heat content change (Gregory et al., 2004; AchutaRao et al., 2006). After the IPCC AR4 report in 2007, time-and depth-dependent systematic errors in bathythermograph temperatures were discovered (Gouretski and Koltermann, 2007; Section 3.2). Bathythermograph data account for a large fraction of the historical temperature observations and are therefore a source of bias in ocean heat content studies. Bias corrections were then developed and applied to observations. With the newer bias-corrected estimates (Domingues et al., 2008; Wijffels et al., 2008; Ishii and Kimoto, 2009; Levitus et al., 2009), it became obvious that the large decadal variability in earlier estimates of global upper-ocean heat content was an observational artefact (Section 3.2).

The interannual to decadal variability of ocean temperature simulated by the CMIP3 models agrees better with observations when the model data is sampled using the observational data mask (AchutaRao et al., 2007). In the upper 700 m, CMIP3 model simulations agreed more closely with observational estimates of global ocean heat content based on bias-corrected ocean temperature data, both in terms of the decadal variability and multi-decadal trend (Figure 10.14a) when forced with the most complete set of natural and anthropogenic forcings (Domingues et al., 2008). For the simulations with the most complete set of forcings, the multi-model ensemble mean trend was only 10% smaller than observed for 1961–1999. Model simulations that included only anthropogenic forcing (i.e., no solar or volcanic forcing) significantly overestimate the multi-decadal trend and underestimate decadal variability. This overestimate of the trend is partially caused by the ocean's response to volcanic eruptions, which results in rapid cooling followed by decadal or longer time variations during the recovery phase. Although it has been suggested (Gregory, 2010) that the cooling trend from successive volcanic events is an artefact because models were not spun up with volcanic forcing, this discrepancy is not expected to be as significant in the upper ocean as in the deeper layers where longer term adjustments take place (Gregory et al., 2012). Thus for the upper ocean, there is *high confidence* that the more frequent eruptions during the second half of the 20th century have caused a multi-decadal cooling that partially offsets the anthropogenic warming and contributes to the apparent decadal variability (Church et al., 2005; Delworth et al., 2005; Fyfe, 2006; Gleckler et al., 2006; Gregory et al., 2006; AchutaRao et al., 2007; Domingues et al., 2008; Palmer et al., 2009; Stenchikov et al., 2009).

Gleckler et al. (2012) examined the detection and attribution of upper-ocean warming in the context of uncertainties in the underlying observational data sets, models and methods. Using three bias-corrected observational estimates of upper-ocean temperature changes (Domingues et al., 2008; Ishii and Kimoto, 2009; Levitus et al., 2009) and models from the CMIP3 multi-model archive, they found that multi-decadal trends in the observations were best understood by including contributions from both natural and anthropogenic forcings. The anthropogenic fingerprint in observed upper-ocean warming, driven by global mean and basin-scale pattern changes, was also detected. The strength of this signal (estimated from successively longer trend periods of ocean heat content starting from 1970) crossed the 5% and 1% significance threshold in 1980 and progressively becomes more strongly detected for longer trend periods (Figure 10.14b), for all ocean heat content time series. This stronger detection for longer periods occurs because the noise (standard deviation of trends in the unforced chang-

es in pattern similarity from model control runs) tends to decrease for longer trend lengths. On decadal time scales, there is *limited evidence* that basin scale space-time variability structure of CMIP3 models is approximately 25% lower than the (poorly constrained) observations, this underestimate is far less than the factor of 2 needed to throw the anthropogenic fingerprint into question. This result is robust to a number of known observational, model, methodological and structural uncertainties.

An analysis of upper-ocean (0 to 700 m) temperature changes for 1955–2004, using bias-corrected observations and 20 global climate models from CMIP5 (Pierce et al., 2012) builds on previous detection and attribution studies of ocean temperature (Barnett et al., 2001, 2005; Pierce et al., 2006). This analysis found that observed temperature changes during the above period are inconsistent with the effects of natural climate variability. That is signal strengths are separated from zero at the 5% significance level, and the probability that the

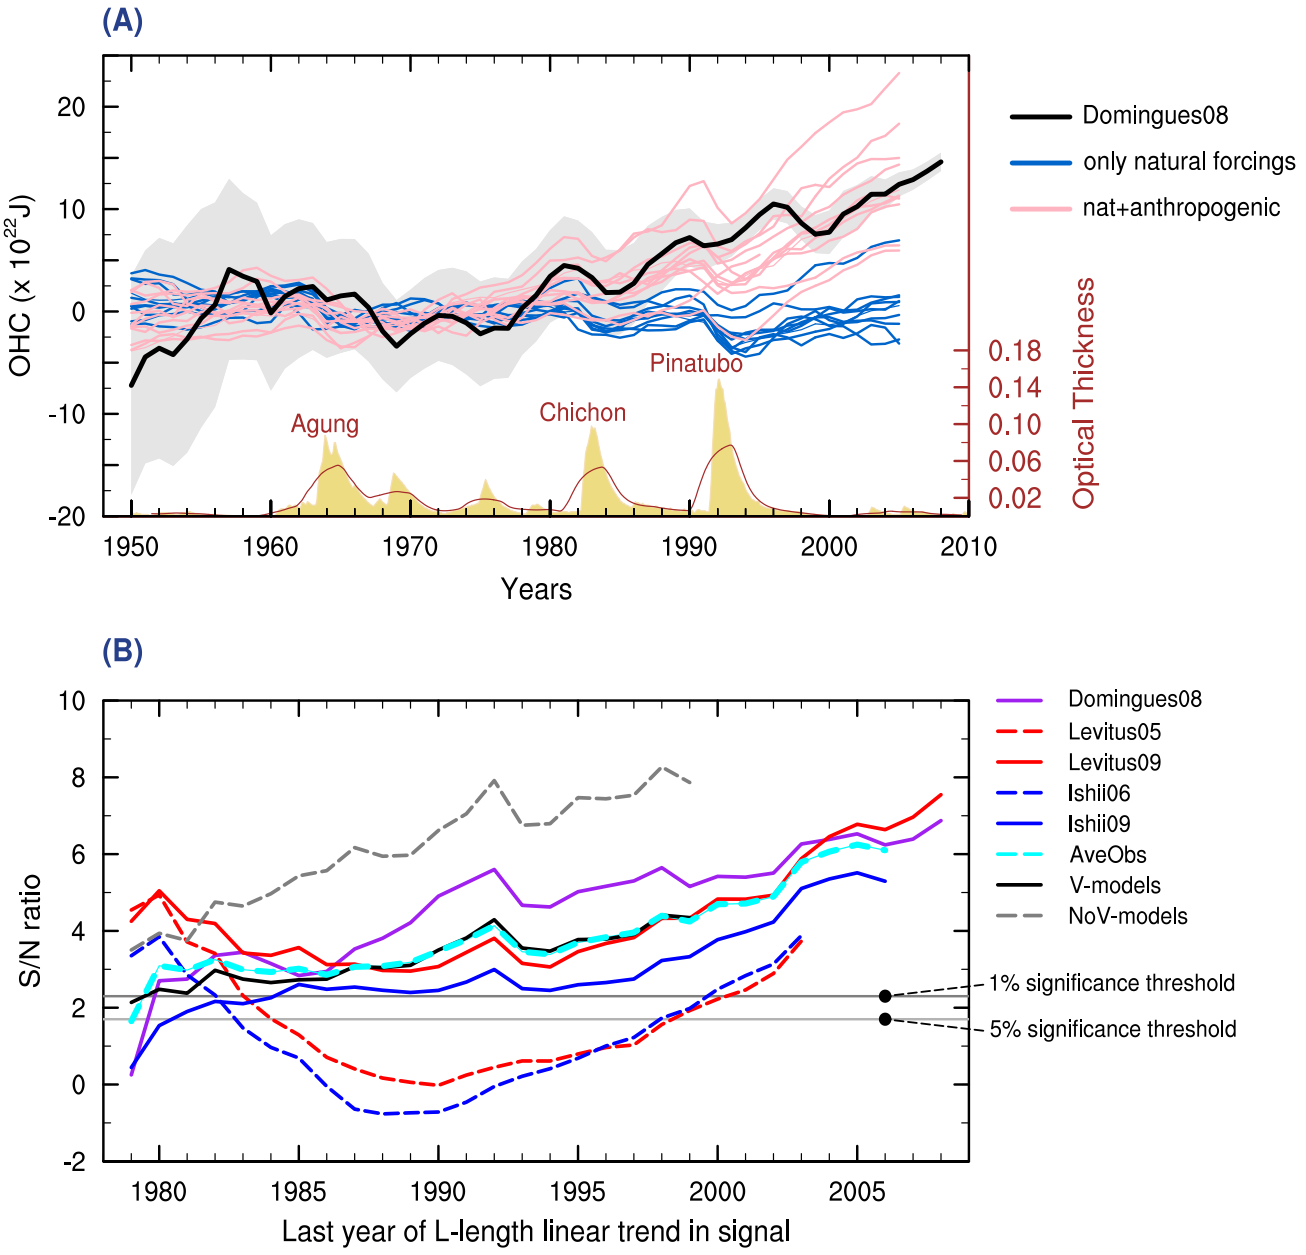

Figure 10.14 | (A) Comparison of observed global ocean heat content for the upper 700 m (updated from Domingues et al. 2008) with simulations from ten CMIP5 models that included only natural forcings ('HistoricalNat' runs shown in blue lines) and simulations that included natural and anthropogenic forcings ('Historical' runs in pink lines). Grey shading shows observational uncertainty. The global mean stratospheric optical depth (Sato et al., 1993) in beige at the bottom indicates the major volcanic eruptions and the brown curve is a 3-year running average of these values. (B) Signal-to-noise (S/N) ratio (plotted as a function of increasing trend length L) of basin-scale changes in volume averaged temperature of newer, expendable bathythermograph (XBT)-corrected data (solid red, purple and blue lines), older, uncorrected data (dashed red and blue lines); the average of the three corrected observational sets (AveObs; dashed cyan line); and simulations that include volcanic (V) or exclude volcanic eruptions (NoV) (black solid and grey dashed lines respectively). The start date for the calculation of signal trends is 1970 and the initial trend length is 10 years. The 1% and 5% significance thresholds are shown (as horizontal grey lines) and assume a Gaussian distribution of noise trends in the V-models control-run pseudo-principal components. The detection time is defined as the year at which S/N exceeds and remains above 1% or 5% significance threshold (Gleckler et al., 2012).

null hypothesis of observed changes being consistent with natural variability is less than 0.05 from variability either internal to the climate system alone, or externally forced by solar fluctuations and volcanic eruptions. However, the observed ocean changes are consistent with those expected from anthropogenically induced atmospheric changes from GHGs and aerosol concentrations.

Attribution to anthropogenic warming from recent detection and attribution studies (Gleckler et al., 2012; Pierce et al., 2012) have made use of new bias-corrected observations and have systematically explored methodological uncertainties, yielding more confidence in the results. With greater consistency and agreement across observational data sets and resolution of structural issues, the major uncertainties at the time of AR4 have now largely been resolved. The high levels of confidence and the increased understanding of the contributions from both natural and anthropogenic sources across the many studies mean that it is *very likely* that the increase in global ocean heat content observed in the upper 700 m since the 1970s has a substantial contribution from anthropogenic forcing.

Although there is *high confidence* in understanding the causes of global heat content increases, attribution of regional heat content changes are less certain. Earlier regional studies used a fixed depth data and only considered basin-scale averages (Barnett et al., 2005). At regional scales, however, changes in advection of ocean heat are important and need to be isolated from changes due to air–sea heat fluxes (Palmer et al., 2009; Grist et al., 2010). Their fixed isotherm (rather than fixed depth) approach to optimal detection analysis, in addition to being largely insensitive to observational biases, is designed to separate the ocean's response to air–sea flux changes from advective changes. Air–sea fluxes are the primary mechanism by which the oceans are expected to respond to externally forced anthropogenic and natural volcanic influences. The finer temporal resolution of the analysis allowed Palmer et al. (2009) to attribute distinct short-lived cooling episodes to major volcanic eruptions while, at multi-decadal time scales, a more spatially uniform near-surface (~ upper 200 m) warming pattern was detected across all ocean basins (except in high latitudes where the isotherm approach has limitations due to outcropping of isotherms at the ocean surface) and attributed to anthropogenic causes at the 5% significance level. Considering that individual ocean basins are affected by different observational and modelling uncertainties and that internal variability is larger at smaller scales, detection of significant anthropogenic forcing through space and time studies (Palmer et al., 2009; Pierce et al., 2012) provides more compelling evidence of human influence at regional scales of near-surface ocean warming observed during the second half of the 20th century.

10.4.2 Ocean Salinity and Freshwater Fluxes

There is increasing recognition of the importance of ocean salinity as an essential climate variable (Doherty et al., 2009), particularly for understanding the hydrological cycle. In the IPCC Fourth Assessment Report observed ocean salinity change indicated that there was a systematic pattern of increased salinity in the shallow subtropics and a tendency to freshening of waters that originate in the polar regions (Bindoff et al., 2007; Hegerl et al., 2007b) (Figure 10.15a, upper and lower panels). New atlases and revisions of the earlier work based on the increasing number of the Array for Real-time Geostrophic Oceanography (ARGO) profile data, and historical data have extended the observational salinity data sets allowing the examination of the long-term changes at the surface and in the interior of the ocean (Section 3.3) and supporting analyses of precipitation changes over land (see Sections 10.3.2.2 and 2.5.1).

Patterns of subsurface salinity changes largely follow the existing mean salinity pattern at the surface and within the ocean. For example, the inter-basin contrast between the Atlantic (salty) and Pacific Oceans (fresh) has intensified over the observed record (Boyer et al., 2005; Hosoda et al., 2009; Roemmich and Gilson, 2009; von Schuckmann et al., 2009; Durack and Wijffels, 2010). In the Southern Ocean, many studies show a coherent freshening of Antarctic Intermediate Water that is subducted at about 50°S (Johnson and Orsi, 1997; Wong et al., 1999; Bindoff and McDougall, 2000; Curry et al., 2003; Boyer et al., 2005; Roemmich and Gilson, 2009; Durack and Wijffels, 2010; Helm et al., 2010; Kobayashi et al., 2012). There is also a clear increase in salinity of the high-salinity subtropical waters (Durack and Wijffels, 2010; Helm et al., 2010).

The 50-year trends in surface salinity show that there is a strong positive correlation between the mean climate of the surface salinity and its temporal changes from 1950 to 2000 (see Figures 3.4 and 10.15b 'ocean obs' point). The correlation between the climate and the trends in surface salinity of 0.7 implies that fresh surface waters get fresher, and salty waters get saltier (Durack et al., 2012). Such patterns of surface salinity change are also found in Atmosphere–Ocean General Circulation Models (AOGCM) simulations both for the 20th century and projected future changes into the 21st century (Figure 10.15b). The pattern of temporal change in observations from CMIP3 simulations is particularly strong for those projections using Special Report on Emission Scenarios (SRES) with larger global warming changes (Figure 10.15b). For the period 1950–2000 the observed amplification of the surface salinity is 16 ± 10% per °C of warming and is twice the simulated surface salinity change in CMIP3 models. This difference between the surface salinity amplification is plausibly caused by the tendency of CMIP3 ocean models mixing surface salinity into deeper layers and consequently surface salinity increases at a slower rate than observed (Durack et al., 2012).

Although there are now many established observed long-term trends of salinity change at the ocean surface and within the interior ocean at regional and global scales (Section 3.3), there are relatively few studies that attribute these changes formally to anthropogenic forcing. Analysis at the regional scale of the observed recent surface salinity increases in the North Atlantic (20°N to 50°N) show a small signal that could be attributed to anthropogenic forcings but for this ocean is not significant compared with internal variability (Stott et al., 2008a; Terray et al., 2012; and Figure 10.15c). On a larger spatial scale, the surface salinity patterns in the band from 30°S to 50°N show anthropogenic contributions that are larger than the 5 to 95% uncertainty range (Terray et al., 2012). The strongest signals that can be attributed to anthropogenic forcing are in the tropics (TRO, 30°S to 30°N) and the western Pacific. These results also show the salinity contrast between the Pacific and Atlantic oceans is also enhanced with significant contributions from anthropogenic forcing.

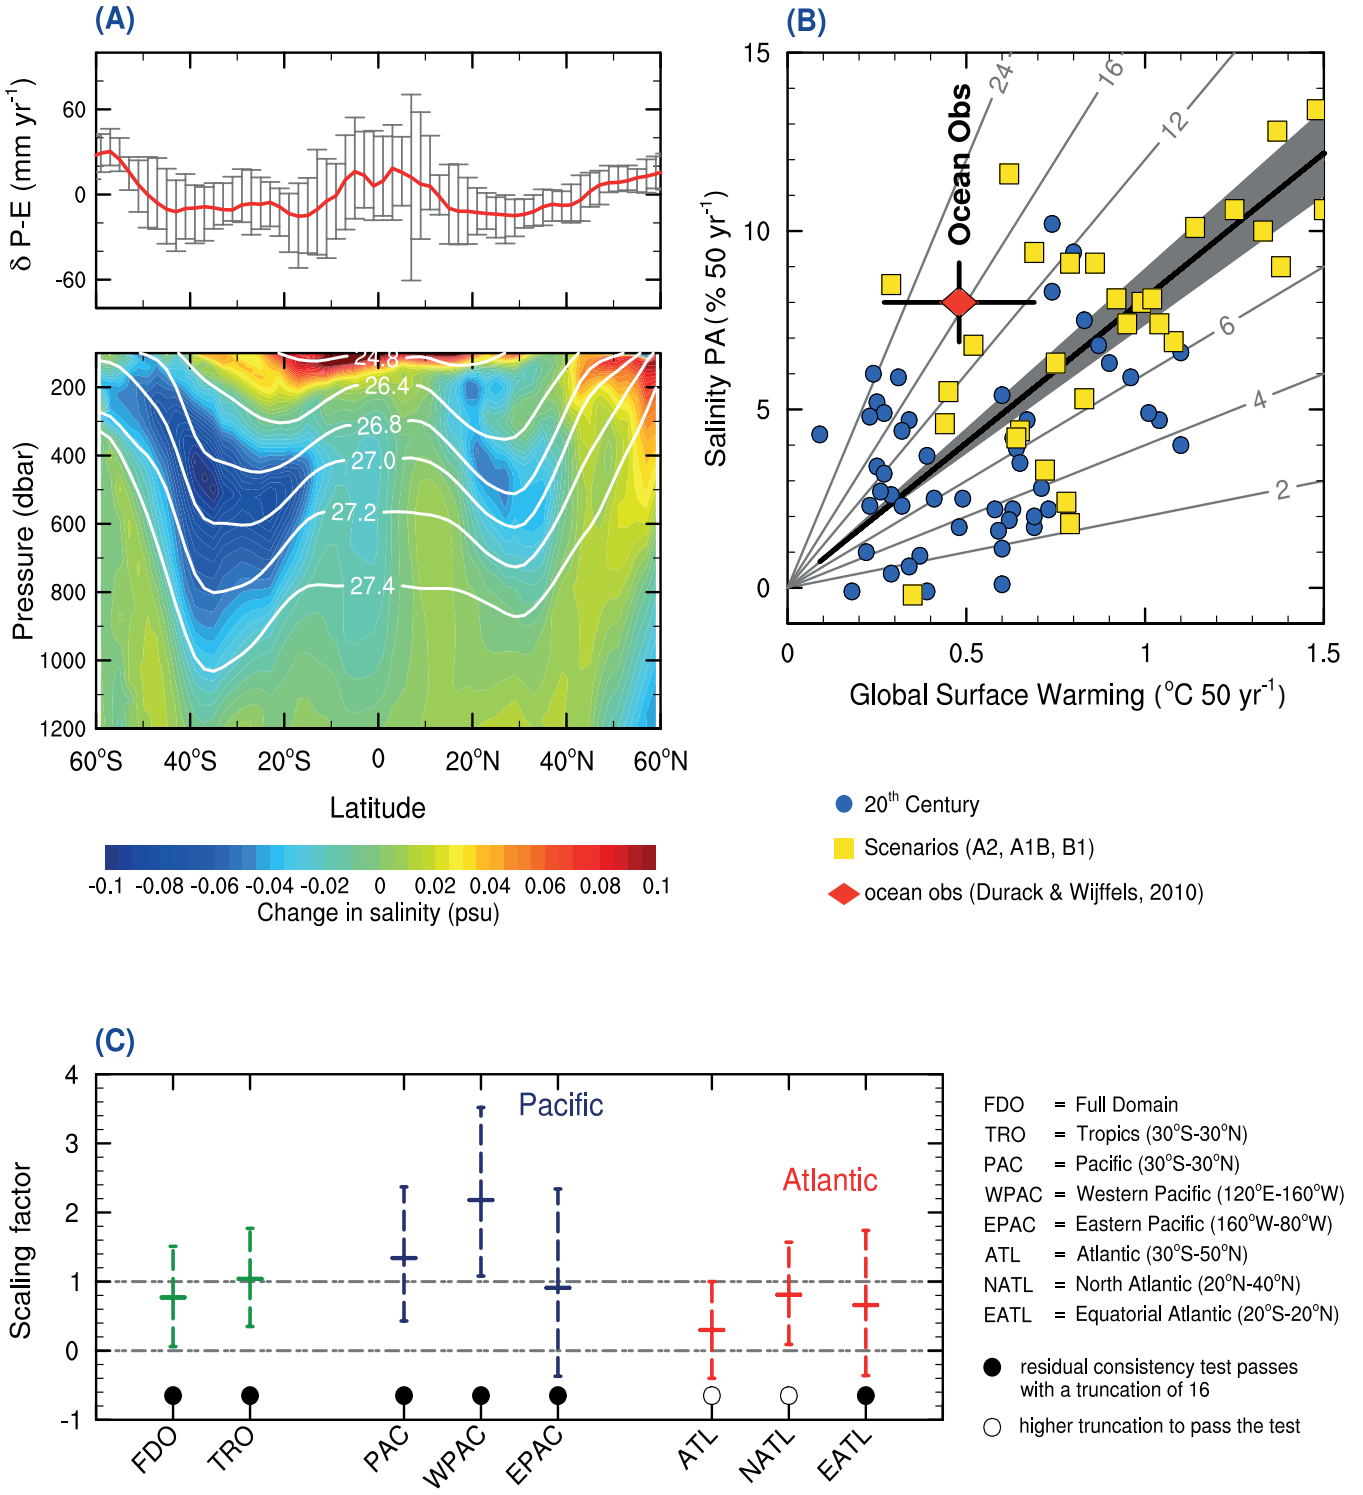

Figure 10.15 | Ocean salinity change and hydrologic cycle. (A) Ocean salinity change observed in the interior of the ocean (A, lower panel in practical salinity units or psu, and white lines are surfaces of constant density) and comparison with ten CMIP3 model projections of precipitation minus evaporation δ (P – E) in mm yr^{-1} for the same period as the observed changes (1970 to 1990s) (A, top panel, red line is the mean of the simulations and error bars are the simulated range). (B) The amplification of the current surface salinity pattern over a 50-year period as a function of global temperature change. Ocean surface salinity pattern amplification has a 16% increase for the 1950–2000 period (red diamond, see text and Section 3.3). Also on this panel CMIP3 simulations from Special Report on Emission Scenarios (SRES) (yellow squares) and from 20th century simulations (blue circles). A total of 93 simulations have been used. (C) Regional detection and attribution in the equatorial Pacific and Atlantic Oceans for 1970 to 2002. Scaling factors for all forcings (anthropogenic) fingerprint are shown (see Box 10.1) with their 5 to 95% uncertainty range, estimated using the total least square approach. Full domain (FDO, 30°S to 50°N), Tropics (TRO, 30°S to 30°N), Pacific (PAC, 30°S to 30°N), west Pacific (WPAC, 120°E to 160°W), east Pacific (EPAC, 160°W to 80°W), Atlantic (ATL, 30°S to 50°N), subtropical north Atlantic (NATL, 20°N to 40°N) and equatorial Atlantic (EATL, 20°S to 20°N) factors are shown. Black filled dots indicate when the residual consistency test passes with a truncation of 16 whereas empty circles indicate a higher truncation was needed to pass the consistency test. Horizontal dashed lines indicate scaling factor of 0 or 1. (A, B and C are adapted from Helm et al. (2010), Durack et al. (2012) and Terray et al. (2012), respectively.)

On a global scale surface and subsurface salinity changes (1955–2004) over the upper 250 m of the water column cannot be explained by natural variability (probability is <0.05) (Pierce et al., 2012). However, the observed salinity changes match the model distribution of forced changes (GHG and tropospheric aerosols), with the observations typically falling between the 25th and 75th percentile of the model distribution at all depth levels for salinity (and temperature). Natural external variability taken from the simulations with just solar and volcanic variations in forcing do not match the observations at all, thus excluding the hypothesis that observed trends can be explained by just solar or volcanic variations.

The results from surface salinity trends and changes are consistent with the results from studies of precipitation over the tropical ocean from the shorter satellite record (Wentz et al., 2007; Allan et al., 2010). These surface salinity results are also consistent with our understanding of the thermodynamic response of the atmosphere to warming (Held and Soden, 2006; Stephens and Hu, 2010) and the amplification of the water cycle. The large number of studies showing patterns of change consistent with amplification of the water cycle, and the detection and attribution studies for the tropical oceans (Terray et al., 2012) and the global pattern of ocean salinity change (Pierce et al., 2012), when combined with our understanding of the physics of the water cycle and estimates of internal climate variability, give *high confidence* in our understanding of the drivers of surface and near surface salinity changes. It is *very likely* that these salinity changes have a discernable contribution from anthropogenic forcing since the 1960s.

10.4.3 Sea Level

At the time of the AR4, the historical sea level rise budget had not been closed (within uncertainties), and there were few studies quantifying the contribution of anthropogenic forcing to the observed sea level rise and glacier melting. Relying on expert assessment, the AR4 had concluded based on modelling and ocean heat content studies that ocean warming and glacier mass loss had *very likely* contributed to sea level rise during the latter half of the 20th century. The AR4 had reported that climate models that included anthropogenic and natural forcings simulated the observed thermal expansion since 1961 reasonably well, and that it is *very unlikely* that the warming during the past half century is due only to known natural causes (Hegerl et al., 2007b).

Since the AR4, corrections applied to instrumental errors in ocean temperature measurements have considerably improved estimates of upper-ocean heat content (see Sections 3.2 and 10.4.1), and therefore ocean thermal expansion. Closure of the global mean sea level rise budget as an evolving time series since the early1970s (Church et al., 2011) indicates that the two major contributions to the rate of global mean sea level rise have been thermal expansion and glacier melting with additional contributions from Greenland and Antarctic ice sheets. Observations since 1971 indicate with *high confidence* that thermal expansion and glaciers (excluding the glaciers in Antarctica) explain 75% of the observed rise (see Section 13.3.6). Ice sheet contributions remain the greatest source of uncertainty over this period and on longer time scales. Over the 20th century, the global mean sea level rise budget (Gregory et al., 2012) has been another important step in understanding the relative contributions of different drivers. The observed contribution from thermal expansion is well captured in climate model simulations with historical forcings as are contributions from glacier melt when simulated by glacier models driven by climate model simulations of historical climate (Church et al., 2013; Table 13.1). The model results indicate that most of the variation in the contributions of thermal expansion and glacier melt to global mean sea level is in response to natural and anthropogenic RFs (Domingues et al., 2008; Palmer et al., 2009; Church et al., 2013).

The strong physical relationship between thermosteric sea level and ocean heat content (through the equation of state for seawater) means that the anthropogenic ocean warming (Section 10.4.1) has contributed to global sea level rise over this period through thermal expansion. As Section 10.5.2 concludes, it is *likely* that the observed substantial mass loss of glaciers is due to human influence and that it is *likely* that anthropogenic forcing and internal variability are both contributors to recent observed changes on the Greenland ice sheet. The causes of recently observed Antarctic ice sheet contribution to sea level are less clear due to the short observational record and incomplete understanding of natural variability. Taking the causes of Greenland ice sheet melt and glacier mass loss together (see Section 10.5.2), it is concluded with *high confidence* that it is *likely* that anthropogenic forcing has contributed to sea level rise from melting glaciers and ice sheets. Combining the evidence from ocean warming and mass loss of glaciers we conclude that it is *very likely* that there is a substantial contribution from anthropogenic forcing to the global mean sea level rise since the 1970s.

On ocean basin scales, detection and attribution studies do show the emergence of detectable signals in the thermosteric component of sea level that can be largely attributed to human influence (Barnett et al., 2005; Pierce et al., 2012). Regional changes in sea level at the sub-ocean basin scales and finer exhibit more complex variations associated with natural (dynamical) modes of climate variability (Section 13.6). In some regions, sea level trends have been observed to differ significantly from global mean trends. These have been related to thermosteric changes in some areas and in others to changing wind fields and resulting changes in the ocean circulation (Han et al., 2010; Timmermann et al., 2010; Merrifield and Maltrud, 2011). The regional variability on decadal and longer time scales can be quite large (and is not well quantified in currently available observations) compared to secular changes in the winds that influence sea level. Detection of human influences on sea level at the regional scale (that is smaller than sub-ocean basin scales) is currently limited by the relatively small anthropogenic contributions compared to natural variability (Meyssignac et al., 2012) and the need for more sophisticated approaches than currently available.

10.4.4 Oxygen and Ocean Acidity

Oxygen is an important physical and biological tracer in the ocean (Section 3.8.3) and is projected to decline by 3 to 6% by 2100 in response to surface warming (see Section 6.4.5). Oxygen decreases are also observed in the atmosphere and linked to burning of fossil fuels (Section 6.1.3.2). Despite the relatively few observational studies of oxygen change in the oceans (Bindoff and McDougall, 2000; Ono et al., 2001; Keeling and Garcia, 2002; Emerson et al., 2004; Aoki et al., 2005;

Mecking et al., 2006; Nakanowatari et al., 2007; Brandt et al., 2010) they all show a pattern of change consistent with the known ocean circulation and surface ventilation. A recent global analysis of oxygen data from the 1960s to 1990s for change confirm these earlier results and extends the spatial coverage from local to global scales (Helm et al., 2011). The strongest decreases in oxygen occur in the mid-latitudes of both hemispheres, near regions where there is strong water renewal and exchange between the ocean interior and surface waters. The attribution study of oxygen decreases using two Earth System Models (ESMs) concluded that observed changes for the Atlantic Ocean are 'indistinguishable from natural internal variability'; however, the changes of the global zonal mean to external forcing (all forcings including GHGs) has a detectable influence at the 10% significance level (Andrews et al., 2013). The chief sources of uncertainty are the paucity of oxygen observations, particularly in time, the precise role of the biological pump and changes in ocean productivity in the models (see Sections 3.8.3 and 6.4.5), and model circulation biases particularly near the oxygen minimum zone in tropical waters (Brandt et al., 2010; Keeling et al., 2010; Stramma et al., 2010). These results of observed changes in oxygen and the attribution studies of oxygen changes (Andrews et al., 2013), along with the attribution of human influences on the physical factors that affect oxygen in the oceans such as surface temperatures changes (Section 10.3.2), increased ocean heat content (Section 10.4.1) and observed increased in ocean stratification (Section 3.2.2) provides evidence for human influence on oxygen. When these lines of evidence are taken together it is concluded that with *medium confidence* or *about as likely as not* that the observed oxygen decreases can be attributed in part to human influences.

The observed trends (since the 1980s) for ocean acidification and its cause from rising CO_2 concentrations is discussed in Section 3.8.2 (Box 3.2 and Table 10.1). There is *very high* confidence that anthropogenic CO_2 has resulted in the acidification of surface waters of between –0.0015 and –0.0024 pH units per year.

10.5 Cryosphere

This section considers changes in sea ice, ice sheets and ice shelves, glaciers, snow cover. The assessment of attribution of human influences on temperature over the Arctic and Antarctica is in Section 10.3.1.

10.5.1 Sea Ice

10.5.1.1 Arctic and Antarctic Sea Ice

The Arctic cryosphere shows large observed changes over the last decade as noted in Chapter 4 and many of these shifts are indicators of major regional and global feedback processes (Kattsov et al., 2010). An assessment of sea ice models' capacity to simulate Arctic and Antarctic sea ice extent is given in Section 9.4.3. Of principal importance is 'Arctic Amplification' (see Box 5.1) where surface temperatures in the Arctic are increasing faster than elsewhere in the world.

The rate of decline of Arctic sea ice thickness and September sea ice extent has increased considerably in the first decade of the 21st century (Maslanik et al., 2007; Nghiem et al., 2007; Comiso and Nishio, 2008; Deser and Teng, 2008; Zhang et al., 2008; Alekseev et al., 2009; Comiso, 2012; Polyakov et al., 2012). Based on a sea ice reanalysis and verified by ice thickness estimates from satellite sensors, it is estimated that three quarters of summer Arctic sea ice volume has been lost since the 1980s (Schweiger et al., 2011; Maslowski et al., 2012; Laxon et al., 2013; Overland and Wang, 2013). There was also a rapid reduction in ice extent, to 37% less in September 2007 and to 49% less in September 2012 relative to the 1979–2000 climatology (Figure 4.11, Section 4.2.2). Unlike the loss record set in 2007 that was dominated by a major shift in climatological winds, sea ice loss in 2012 was more due to a general thinning of the sea ice (Lindsay et al., 2009; Wang et al., 2009a; Zhang et al., 2013). All recent years have ice extents that fall at least two standard deviations below the long-term sea ice trend.

The amount of old, thick multi-year sea ice in the Arctic has decreased by 50% from 2005 through 2012 (Giles et al., 2008; Kwok et al., 2009; Kwok and Untersteiner, 2011 and Figures 4.13 and 4.14). Sea ice has also become more mobile (Gascard et al., 2008). We now have seven years of data that show sea ice conditions are substantially different to that observed prior to 2006. The relatively large increase in the percentage of first year sea ice across the Arctic basin can be considered 'a new normal.'

Confidence in detection of change comes in part from the consistency of multiple lines of evidence. Since AR4, evidence has continued to accumulate from a range of observational studies that systematic changes are occurring in the Arctic. Persistent trends in many Arctic variables, including sea ice, the timing of spring snow melt, increased shrubbiness in tundra regions, changes in permafrost, increased area of forest fires, changes in ecosystems, as well as Arctic-wide increases in air temperatures, can no longer be associated solely with the dominant climate variability patterns such as the Arctic Oscillation, Pacific North American pattern or Atlantic Meridional Oscillation (AMO) (Quadrelli and Wallace, 2004; Vorosmarty et al., 2008; Overland, 2009; Brown and Robinson, 2011; Mahajan et al., 2011; Oza et al., 2011a; Wassmann et al., 2011; Nagato and Tanaka, 2012). Duarte et al. (2012) completed a meta-analysis showing evidence from multiple indicators of detectable climate change signals in the Arctic.

The increase in the magnitude of recent Arctic temperature and decrease in sea ice volume and extent are hypothesized to be due to coupled Arctic amplification mechanisms (Serreze and Francis, 2006; Miller et al., 2010). These feedbacks in the Arctic climate system suggest that the Arctic is sensitive to external forcing (Mahlstein and Knutti, 2012). Historically, changes were damped by the rapid formation of sea ice in autumn causing a negative feedback and a rapid seasonal cooling. But recently, the increased mobility and loss of multi-year sea ice, combined with enhanced heat storage in the sea ice-free regions of the Arctic Ocean form a connected set of processes with positive feedbacks causing an increase in Arctic temperatures and a decrease in sea ice extent (Manabe and Wetherald, 1975; Gascard et al., 2008; Serreze et al., 2009; Stroeve et al., 2012a, 2012b) . In addition to the well known *ice albedo* feedback where decreased sea ice cover decreases the amount of *insolation* reflected from the surface, there is a late summer/early autumn positive *ice insulation* feedback due to additional ocean heat storage in areas previously covered by sea ice

(Jackson et al., 2010). Arctic amplification may also have a contribution from poleward heat transport in the atmosphere and ocean (Langen and Alexeev, 2007; Graversen and Wang, 2009; Doscher et al., 2010; Yang et al., 2010).

It appears that recent Arctic changes are in response to a combination of global-scale warming, from warm anomalies from internal climate variability on different time scales, and are amplified from the multiple feedbacks described above. For example, when the 2007 sea ice minimum occurred, Arctic temperatures had been rising and sea ice extent had been decreasing over the previous two decades (Stroeve et al., 2008; Screen and Simmonds, 2010). Nevertheless, it took unusually persistent southerly winds along the dateline over the summer months to initiate the sea ice loss event in 2007 (Zhang et al., 2008; Wang et al., 2009b). Similar southerly wind patterns in previous years did not initiate major reductions in sea ice extent because the sea ice was too thick to respond (Overland et al., 2008). Increased oceanic heat transport through the Barents Sea in the first decade of the 21st century and the AMO on longer time scales may also have played a role in determining sea ice anomalies in the Atlantic Arctic (Dickson et al., 2000; Semenov, 2008; Zhang et al., 2008; Day et al., 2012) . Based on the evidence in the previous paragraphs there is *high confidence* that these Arctic amplification mechanisms are currently affecting regional Arctic climate. But it also suggests that the timing of future major sea ice loss events will be difficult to project. There is evidence therefore that internal variability of climate, long-term warming, and Arctic Amplification feedbacks have all contributed to recent decreases in Arctic sea ice (Kay et al., 2011b; Kinnard et al., 2011; Overland et al., 2011; Notz and Marotzke, 2012).

Turning to model-based attribution studies, Min et al. (2008b) compared the seasonal evolution of Arctic sea ice extent from observations with those simulated by multiple General Circulation Models (GCMs) for 1953–2006. Comparing changes in both the amplitude and shape of the annual cycle of the sea ice extent reduces the chance of spurious detection due to coincidental agreement between the response to anthropogenic forcing and other factors, such as slow internal variability. They found that human influence on the sea ice extent changes has been robustly detected since the early 1990s. The anthropogenic signal is also detectable for individual months from May to December, suggesting that human influence, strongest in late summer, now also extends into colder seasons. Kay et al. (2011b), Jahn et al. (2012) and Schweiger et al. (2011) used the Community Climate System Model 4 (CCSM4) to investigate the influence of anthropogenic forcing on late 20th century and early 21st century Arctic sea ice extent and volume trends. On all time scales examined (2 to 50+ years), the most extreme negative extent trends observed in the late 20th century cannot be explained by modeled internal variability alone. Comparing trends from the CCSM4 ensemble to observed trends suggests that internal variability could account for approximately half of the observed 1979–2005 September Arctic sea ice extent loss. Attribution of anthropogenic forcing is also shown by comparing September sea ice extent as projected by seven models from the set of CMIP5 models' hindcasts to control runs without anthropogenic forcing (Figure 10.16a; Wang and Overland, 2009). The mean of sea ice extents in seven models' ensemble members are below the level of their control runs by about 1995, similar to the result of Min et al. (2008b).

A question as recently as 6 years ago was whether the recent Arctic warming and sea ice loss was unique in the instrumental record and whether the observed trend would continue (Serreze et al., 2007). Arctic temperature anomalies in the 1930s were apparently as large as those in the 1990s and 2000s. There is still considerable discussion of the ultimate causes of the warm temperature anomalies that occurred in the Arctic in the 1920s and 1930s (Ahlmann, 1948; Veryard, 1963; Hegerl et al., 2007a, 2007b). The early 20th century warm period, while reflected in the hemispheric average air temperature record (Brohan et al., 2006), did not appear consistently in the mid-latitudes nor on the Pacific side of the Arctic (Johannessen et al., 2004; Wood and Overland, 2010). Polyakov et al. (2003) argued that the Arctic air temperature records reflected a natural cycle of about 50 to 80 years. However, many authors (Bengtsson et al., 2004; Grant et al., 2009; Wood and Overland, 2010; Brönnimann et al., 2012) instead link the 1930s temperatures to internal variability in the North Atlantic atmospheric and ocean circulation as a single episode that was sustained by ocean and sea ice processes in the Arctic and north Atlantic. The Arctic-wide increases of temperature in the last decade contrast with the episodic regional increases in the early 20th century, suggesting that it is unlikely that recent increases are due to the same primary climate process as the early 20th century.

In the case of the Arctic we have *high confidence* in observations since 1979, from models (see Section 9.4.3 and from simulations comparing with and without anthropogenic forcing), and from physical understanding of the dominant processes; taking these three factors together it is *very likely* that anthropogenic forcing has contributed to the observed decreases in Arctic sea ice since 1979.

Whereas sea ice extent in the Arctic has decreased, sea ice extent in the Antarctic has *very likely* increased (Section 4.2.3). Sea ice extent across the SH over the year as a whole increased by 1.3 to 1.67% per decade from 1979 to 2012, with the largest increase in the Ross Sea during the autumn, while sea ice extent decreased in the Amundsen-Bellingshausen Sea (Comiso and Nishio, 2008; Turner et al., 2009, 2013; Section 4.2.3; Oza et al., 2011b). The observed upward trend in Antarctic sea ice extent is found to be inconsistent with internal variability based on the residuals from a linear trend fitted to the observations, though this approach could underestimate multi-decadal variability (Section 4.2.3; Turner et al., 2013; Section 4.2.3; Zunz et al., 2013). The CMIP5 simulations on average simulate a decrease in Antarctic sea ice extent (Turner et al., 2013; Zunz et al., 2013; Figure 10.16b), though Turner et al. (2013) find that approximately 10% of CMIP5 simulations exhibit an increasing trend in Antarctic sea ice extent larger than observed over the 1979–2005 period. However, Antarctic sea ice extent variability appears on average to be too large in the CMIP5 models (Turner et al., 2013; Zunz et al., 2013). Overall, the shortness of the observed record and differences in simulated and observed variability preclude an assessment of whether or not the observed increase in Antarctic sea ice extent is inconsistent with internal variability. Based on Figure 10.16b and Meehl et al. (2007b), the trend of Antarctic sea ice loss in simulations due to changes in forcing is weak (relative to the Arctic) and the internal variability is high, and thus the time necessary for detection is longer than in the Arctic.

Several recent studies have investigated the possible causes of Antarctic sea ice trends. Early studies suggested that stratospheric ozone depletion may have driven increasing trends in Antarctic ice extent (Goosse et al., 2009; Turner et al., 2009; WMO (World Meteorological Organization), 2011), but recent studies demonstrate that simulated sea ice extent decreases in response to prescribed changes in stratospheric ozone (Sigmond and Fyfe, 2010; Bitz and Polvani, 2012). An alternative explanation for the lack of melting of Antarctic sea ice is that sub-surface ocean warming, and enhanced freshwater input possibly in part from ice shelf melting, have made the high-latitude Southern Ocean fresher (see Section 3.3) and more stratified, decreasing the upward heat flux and driving more sea ice formation (Zhang, 2007; Goosse et al., 2009; Bintanja et al., 2013). An idealized simulation of the response to freshwater input similar to that estimate due to ice shelf melting exhibited an increase in sea ice extent (Bintanja et al., 2013), but this result has yet to be reproduced with other models. Overall we conclude that there is *low confidence* in the scientific understanding of the observed increase in Antarctic sea ice extent since 1979, owing to

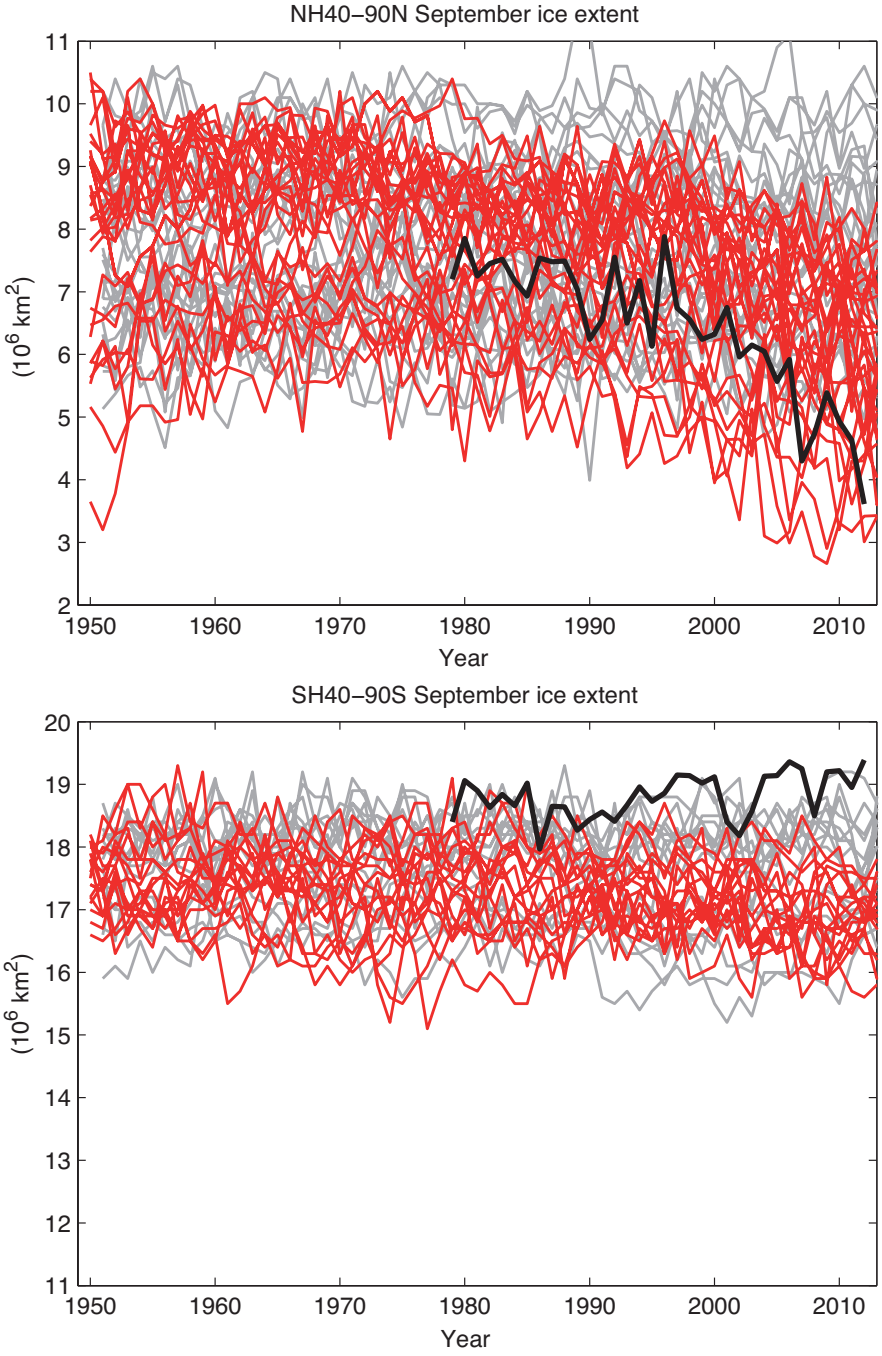

Figure 10.16 | September sea ice extent for Arctic (top) and Antarctic (bottom) adapted from (Wang and Overland, 2012). Only CMIP5 models that simulated seasonal mean and magnitude of seasonal cycle in reasonable agreement with observations are included in the plot. The grey lines are the runs from the pre-industrial control runs, and the red lines are from Historical simulations runs patched with RCP8.5 runs for the period of 2005–2012. The black line is based on data from National Snow and Ice Data Center (NSIDC). There are 24 ensemble members from 11 models for the Arctic and 21 members from 6 models for the Antarctic plot. See Supplementary Material for the precise models used in the top and bottom panel.

the larger differences between sea ice simulations from CMIP5 models and to the incomplete and competing scientific explanations for the causes of change and *low confidence* in estimates of internal variability (Section 9.4.3).

10.5.2 Ice Sheets, Ice Shelves and Glaciers

10.5.2.1 Greenland and Antarctic Ice Sheets

The Greenland and Antarctic ice sheets are important to regional and global climate because (along with other cryospheric elements) they cause a polar amplification of surface temperatures, a source of fresh water to the ocean, and represent a source of potentially irreversible change to the state of the Earth system (Hansen and Lebedeff, 1987). These two ice sheets are important contributors to sea level rise representing two-thirds of the contributions from all ice covered regions (Jacob et al., 2012; Pritchard et al., 2012; see Sections 4.4 and 13.3.3). Observations of surface mass balance (increased ablation versus increased snowfall) are dealt with in Section 4.4.3 and ice sheet models are discussed in Sections 13.3 and 13.5.

Attribution of change is difficult as ice sheet and glacier changes are local and ice sheet processes are not generally well represented in climate models thus precluding formal single-step detection and attribution studies. However, Greenland observational records show large recent changes. Section 13.3 concludes that regional models for Greenland can reproduce trends in the surface mass balance loss quite well if they are forced with the observed meteorological record, but not with forcings from a Global Climate Model. Regional model simulations (Fettweis et al., 2013) show that Greenland surface melt increases nonlinearly with rising temperatures due to the positive feedback between surface albedo and melt.

There have been exceptional changes in Greenland since 2007 marked by record-setting high air temperatures, ice loss by melting and marine-terminating glacier area loss (Hanna et al., 2013; Section 4.4.4). Along Greenland's west coast temperatures in 2010 and 2011were the warmest since record keeping began in 1873 resulting in the highest observed melt rates in this region since 1958 (Fettweis et al., 2011). The annual rate of area loss in marine-terminating glaciers was 3.4 times that of the previous 8 years, when regular observations became available. In 2012, a new record for summertime ice mass loss was two standard deviations below the 2003–2012 mean, as estimated from the Gravity Recovery and Climate Experiment (GRACE) satellite (Tedesco et al., 2012). The trend of summer mass change during 2003–2012 is rather uniform over this period at -29 ± 11 Gt yr^{-1}.

Record surface melts during 2007–2012 summers are linked to persistent atmospheric circulation that favored warm air advection over Greenland. These persistent events have changed in frequency since the beginning of the 2000s (L'Heureux et al., 2010; Fettweis et al., 2011). Hanna et al. (2013) show a weak relation of Greenland temperatures and ice sheet runoff with the AMO; they more strongly correlate with a Greenland atmospheric blocking index. Overland et al. (2012) and Francis and Vavrus (2012) suggest that the increased frequency of the Greenland blocking pattern is related to broader scale Arctic changes. Since 2007, internal variability is *likely* to have further enhanced the melt over Greenland. Mass loss and melt is also occurring in Greenland through the intrusion of warm water into the major glaciers such as Jacobshaven Glacier (Holland et al., 2008; Walker et al., 2009).

Hanna et al. (2008) attribute increased Greenland runoff and melt since 1990 to global warming; southern Greenland coastal and NH summer temperatures were uncorrelated between the 1960s and early 1990s but correlated significantly positively thereafter. This relationship was modulated by the NAO, whose summer index significantly negatively correlated with southern Greenland summer temperatures until the early 1990s but not thereafter. Regional modelling and observations tell a consistent story of the response of Greenland temperatures and ice sheet runoff to shifts in recent regional atmospheric circulation associated with larger scale flow patterns and global temperature increases. It is *likely* that anthropogenic forcing has contributed to surface melting of the Greenland ice sheet since 1993.

There is clear evidence that the West Antarctic ice sheet is contributing to sea level rise (Bromwich et al., 2013). Estimates of ice mass in Antarctic since 2000 show that the greatest losses are at the edges (see Section 4.4). An analysis of observations underneath a floating ice shelf off West Antarctica shows that ocean warming and more transport of heat by ocean circulation are largely responsible for increasing melt rates (Jacobs et al., 2011; Joughin and Alley, 2011; Mankoff et al., 2012; Pritchard et al., 2012).

Antarctica has regionally dependent decadal variability in surface temperature with variations in these trends depending on the strength of the SAM climate pattern. Recent warming in continental west Antarctica has been linked to SST changes in the tropical Pacific (Ding et al., 2011). As with Antarctic sea ice, changes in Antarctic ice sheets have complex causes (Section 4.4.3). The observational record of Antarctic mass loss is short and the internal variability of the ice sheet is poorly understood. Due to a low level of scientific understanding there is *low confidence* in attributing the causes of the observed loss of mass from the Antarctic ice sheet since 1993. Possible future instabilities in the west Antarctic ice sheet cannot be ruled out, but projection of future climate changes over West Antarctica remains subject to considerable uncertainty (Steig and Orsi, 2013).

10.5.2.2 Glaciers

In the 20th century, there is robust evidence that large-scale internal climate variability governs interannual to decadal variability in glacier mass (Hodge et al., 1998; Nesje et al., 2000; Vuille et al., 2008; Huss et al., 2010; Marzeion and Nesje, 2012) and, along with glacier dynamics, impacts glacier length as well (Chinn et al., 2005). On time periods longer than years and decades, there is now evidence of recent ice loss (see Section 4.3.3) due to increased ambient temperatures and associated regional moisture changes. However, few studies evaluate the direct attribution of the current observed mass loss to anthropogenic forcing, owing to the difficulty associated with contrasting scales between glaciers and the large-scale atmospheric circulation (Mölg et al., 2012). Reichert et al. (2002) show for two sample sites at mid and high latitude that internal climate variability over multiple millennia as represented in a GCM would not result in such short glacier lengths as observed in the 20th century. For a sample site at low latitude using

multi-step attribution, Mölg et al. (2009) (and references therein) found a close relation between glacier mass loss and the externally forced atmosphere–ocean circulation in the Indian Ocean since the late 19th century. A second, larger group of studies makes use of century-scale glacier records (mostly glacier length but mass balance as well) to extract evidence for external drivers. These include local and regional changes in precipitation and air temperature, and related parameters (such as melt factors and solid/liquid precipitation ratio) estimated from the observed change in glaciers. In general these studies show that the glacier changes reveal unique departures since the 1970s, and that the inferred climatic drivers in the 20th century and particularly in most recent decades, exceed the variability of the earlier parts of the records (Oerlemans, 2005; Yamaguchi et al., 2008; Huss and Bauder, 2009; Huss et al., 2010; Leclercq and Oerlemans, 2011). These results underline the contrast to former centuries where observed glacier fluctuations can be explained by internal climate variability (Reichert et al., 2002; Roe and O'Neal, 2009; Nussbaumer and Zumbühl, 2012). Anthropogenic land cover change is an unresolved forcing, but a first assessment suggests that it does not confound the impacts of recent temperature and precipitation changes if the land cover changes are of local nature (Mölg et al., 2012). The robustness of the estimates of observed mass loss since the 1960s (Section 4.3, Figure 4.11), the confidence we have in estimates of natural variations and internal variability from long-term glacier records, and our understanding of glacier response to climatic drivers provides robust evidence and, therefore, *high confidence* that a substantial part of the mass loss of glaciers is *likely* due to human influence.

10.5.3 Snow Cover

Both satellite and *in situ* observations show significant reductions in the NH snow cover extent (SCE) over the past 90 years, with most reduction occurring in the 1980s (see Section 4.5). Formal detection and attribution studies have indicated anthropogenic influence on NH SCE (Rupp et al., 2013) and western USA snow water equivalent (SWE, Pierce et al., 2008). Pierce et al. (2008) detected anthropogenic influence in the ratio of 1 April SWE over October to March precipitation over the period 1950–1999. These reductions could not be explained by natural internal climate variability alone, nor by changes in solar and volcanic forcing. In their analysis of NH SCE using 13 CMIP5 simulations over the 1922–2005 period, Rupp et al. (2013) showed that some CMIP5 simulations with natural external and anthropogenic forcings could explain the observed decrease in spring SEC though the CMIP5 simulations with all forcing as a whole could only explain half of the magnitude of decrease, and that volcanic and solar variations (from four CMIP5 simulations) were inconsistent with observations. We conclude with *high confidence* in the observational and modelling evidence that the decrease in NH snow extent since the 1970s is *likely* to be caused by all external forcings and has an anthropogenic contribution (see Table 10.1).

10.6 Extremes

Because many of the impacts of climate changes may manifest themselves through weather and climate extremes, there is increasing interest in quantifying the role of human and other external influences on those extremes. SREX assessed causes of changes in different types of extremes including temperature and precipitation, phenomena that influence the occurrence of extremes (e.g., storms, tropical cyclones), and impacts on the natural physical environment such as drought (Seneviratne et al., 2012). This section assesses current understanding of causes of changes in weather and climate extremes, using AR4 as a starting point. Any changes or modifications to SREX assessment are highlighted.

10.6.1 Attribution of Changes in Frequency/ Occurrence and Intensity of Extremes

This sub-section assesses attribution of changes in the characteristics of extremes including frequency and intensity of extremes. Many of the extremes discussed in this sub-section are moderate extreme events that occur more than once in a year (see Box 2.4 for detailed discussion). Attribution of changes in the risk of specific extreme events, which are also very rare in general, is assessed in the next sub-section.

10.6.1.1 Temperature Extremes

AR4 concluded that 'surface temperature extremes have *likely* been affected by anthropogenic forcing'. Many indicators of climate extremes and variability showed changes consistent with warming, including a widespread reduction in number of frost days in mid-latitude regions and evidence that in many regions warm extremes had become warmer and cold extremes had become less cold. We next assess new studies made since AR4.

Relatively warm seasonal mean temperatures (e.g., those that have a recurrence once in 10 years) have seen a rapid increase in frequency for many regions worldwide (Jones et al., 2008; Stott et al., 2011; Hansen et al., 2012) and an increase in the occurrence frequencies of unusually warm seasonal and annual mean temperatures has been attributed in part to human influence (Stott et al., 2011; Christidis et al., 2012a, 2012b).

A large amount of evidence supports changes in daily data based temperature extreme indices consistent with warming, despite different data sets or different methods for data processing having been used (Section 2.6). The effects of human influence on daily temperature extremes is suggested by both qualitative and quantitative comparisons between observed and CMIP3 based modelled values of warm days and warm nights (the number of days exceeding the 90th percentile of daily maximum and daily minimum temperatures referred to as TX90p and TN90p, see also Section 2.7) and cold days and cold nights (the number of days with daily maximum and daily minimum temperatures below the 10th percentile referred to as TX10p and TN10p; see also Section 2.7). Trends in temperature extreme indices computed for Australia (Alexander and Arblaster, 2009) and the USA (Meehl et al., 2007a) using observations and simulations of the 20th century with nine GCMs that include both anthropogenic and natural forcings are found to be consistent. Both observations and model simulations show a decrease in the number of frost days, and an increase in the growing season length, heatwave duration and TN90p in the second half of the 20th century. Two of the models (PCM and CCSM3) with simulations that include only anthropogenic or only natural forcings

indicate that the observed changes are simulated with anthropogenic forcings, but not with natural forcings (even though there are some differences in the details of the forcings). Morak et al. (2011) found that over many sub-continental regions, the number of warm nights (TN90p) shows detectable changes over the second half of the 20th century that are consistent with model simulated changes in response to historical external forcings. They also found detectable changes in indices of temperature extremes when the data were analysed over the globe as a whole. As much of the long-term change in TN90p can be predicted based on the interannual correlation of TN90p with mean temperature, Morak et al. (2013) conclude that the detectable changes are attributed in a multi-step approach (see Section 10.2.4) in part to GHG increases. Morak et al. (2013) have extended this analysis to TX10p, TN10p, TX90p as well as TN90p, using fingerprints from HadGEM1 and find detectable changes on global scales and in many regions (Figure 10.17).

Human influence has also been detected in two different measures of the intensity of extreme daily temperatures in a year. Zwiers et al. (2011) compared four extreme temperature variables including warmest daily maximum and minimum temperatures (annual maximum daily maximum and minimum temperatures, referred to as TXx, TNx) and coldest daily maximum and minimum temperatures (annual minimum daily maximum and minimum temperatures, referred to as TXn, TNn) from observations and from simulations with anthropogenic forcing or anthropogenic and natural external forcings from seven GCMs. They consider these extreme daily temperatures to follow generalized extreme value (GEV) distributions with location, shape and scale parameters. They fit GEV distributions to the observed extreme temperatures with location parameters as linear functions of signals obtained from the model simulation. They found that both anthropogenic influence and combined influence of anthropogenic and natural forcing can be detected in all four extreme temperature variables at the global scale over the land, and also regionally over many large land areas (Figure 10.17). In a complementary study, Christidis et al. (2011) used an optimal fingerprint method to compare observed and modelled time-varying location parameters of extreme temperature distributions. They detected the effects of anthropogenic forcing on warmest daily temperatures in a single fingerprint analysis, and were able to separate the effects of natural from anthropogenic forcings in a two fingerprint analysis.

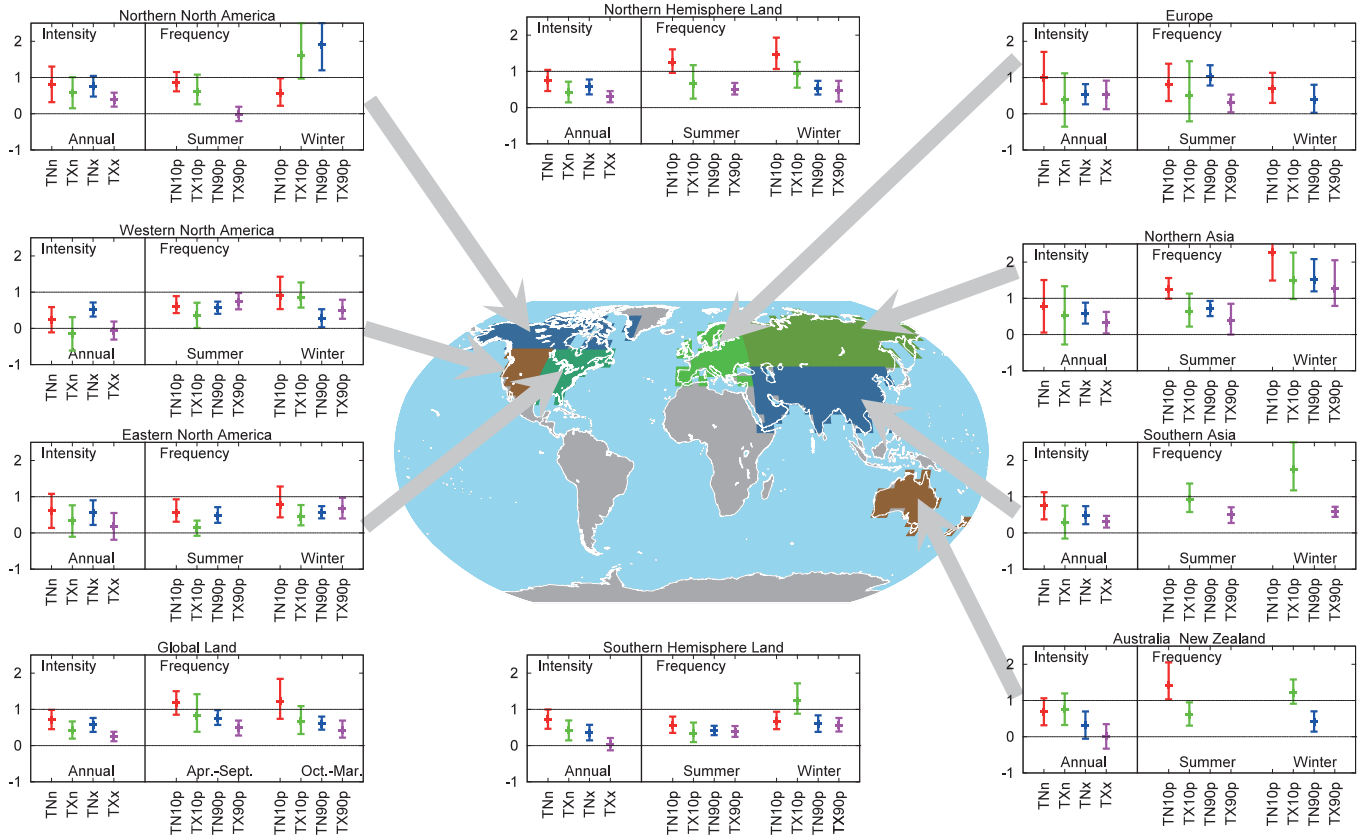

Figure 10.17 | Detection results for changes in intensity and frequency of extreme events. The left side of each panel shows scaling factors and their 90% confidence intervals for intensity of annual extreme temperatures in response to external forcings for the period 1951–2000. TNn and TXn represent coldest daily minimum and maximum temperatures, respectively, while TNx and TXx represent warmest daily minimum and maximum temperatures (updated from Zwiers et al., 2011). Fingerprints are based on simulations of climate models with both anthropogenic and natural forcings. Right-hand sides of each panel show scaling factors and their 90% confidence intervals for changes in the frequency of temperature extremes for winter (October to March for the Northern Hemisphere and April to September for the Southern Hemisphere), and summer half years. TN10p, TX10p are respectively the frequency of cold nights and days (daily minimum and daily maximum temperatures falling below their 10th percentiles for the base period 1961–1990). TN90p and TX90p are the frequency of warm nights and days (daily minimum and daily maximum temperatures above their respective 90th percentiles calculated for the 1961–1990 base period (Morak et al., 2013) with fingerprints based on simulations of Hadley Centre Global Environmental Model 1 (HadGEM1) with both anthropogenic and natural forcings. Detection is claimed at the 5% significance level if the 90% confidence interval of a scaling factor is entirely above the zero line. Grey represents regions with insufficient data.

Human influence on annual extremes of daily temperatures may be detected separately from natural forcing at the global scale (Christidis et al., 2011) and also at continental and sub-continental scales (Min et al., 2013). Over China, Wen et al. (2013) showed that anthropogenic influence may be separately detected from that of natural forcing in daily extreme temperatures (TNn, TNx, TXn and TXx), although the influence of natural forcing is not detected, and they also showed that the influence of GHGs in these indices may be separately detected from other anthropogenic forcings. Christidis et al. (2013) found that on a quasi-global scale, the cooling effect due to the decrease in tree cover and increase in grass cover since pre-industrial times as simulated by one ESM is detectable in the observed change of warm extremes. Urbanization may have also affected extreme temperatures in some regions; for example Zhou and Ren (2011) found that extreme temperature warms more in rural stations than in urban sites in China. The effect of land use change and urban heat Island is found to be small in GMST (Section 2.4.1.3). Consequently, this effect on extreme temperature is also expected to be small in the global average.

These new studies show that there is stronger evidence for anthropogenic forcing on changes in extreme temperatures than at the time of the SREX assessment. New evidence since SREX includes the separation of the influence of anthropogenic forcings from that of natural forcings on extreme daily temperatures at the global scale and to some extent at continental and sub-continental scales in some regions. These new results suggest more clearly the role of anthropogenic forcing on temperature extremes compared to results at the time of the SREX assessment. We assess that it is *very likely* that human influence has contributed to the observed changes in the frequency and intensity of daily temperature extremes on the global scale since the mid-20th century.

10.6.1.2 Precipitation Extremes

Observations have showed a general increase in heavy precipitation at the global scale. This appears to be consistent with the expected response to anthropogenic forcing as a result of an enhanced moisture content in the atmosphere but a direct cause-and-effect relationship between changes in external forcing and extreme precipitation had not been established at the time of the AR4. As a result, the AR4 concluded that increases in heavy precipitation were *more likely than not* consistent with anthropogenic influence during the latter half of the 20th century (Hegerl et al., 2007b).

Extreme precipitation is expected to increase with warming. A combination of evidence leads to this conclusion though by how much remains uncertain and may vary with time scale (Section 7.6.5). Observations and model projected future changes both indicate increase in extreme precipitation associated with warming. Analysis of observed annual maximum 1-day precipitation (RX1day) over global land areas with sufficient data smaples indicates a significant increase in extreme percipitation globally, with a median increase about 7% $°C^{-1}$ GMST increase (Westra et al., 2013). CMIP3 and CMIP5 simulations project an increase in the globally averaged 20-year return values of annual maximum 24-hour precipitation amounts of about 6 to 7% with each degree Celsius of global mean warming, with the bulk of models simulating values in the range of 4 to 10% $°C^{-1}$(Kharin et al., 2007; Kharin et al., 2013). Anthropogenic influence has been detected on various aspects of the global hydrological cycle (Stott et al., 2010), which is directly relevant to extreme precipitation changes. An anthropogenic influence on increasing atmospheric moisture content has been detected (see Section 10.3.2). A higher moisture content in the atmosphere would be expected to lead to stronger extreme precipitation as extreme precipitation typically scales with total column moisture if circulation does not change. An observational analysis shows that winter maximum daily precipitation in North America has statistically significant positive correlations with local atmospheric moisture (Wang and Zhang, 2008).

There is only a modest body of direct evidence that natural or anthropogenic forcing has affected global mean precipitation (see Section 10.3.2 and Figure 10.10), despite a robust expectation of increased precipitation (Balan Sarojini et al., 2012) and precipitation extremes (see Section 7.6.5). However, mean precipitation is expected to increase less than extreme precipitation because of energy constraints (e.g., Allen and Ingram, 2002). A perfect model analysis with an ensemble of GCM simulations shows that anthropogenic influence should be detectable in precipitation extremes in the second half of the 20th century at global and hemispheric scales, and at continental scale as well but less robustly (Min et al., 2008c), see also Hegerl et al. (2004). One study has also linked the observed intensification of precipitation extremes (including RX1day and annual maximum 5-day precipitation (RX5day)) over NH land areas to human influence using a limited set of climate models and observations (Min et al., 2011). However, the detection was less robust if using the fingerprint for combined anthropogenic and natural influences compared to that for anthropogenic influences only, possibly due to a number of factors including weak S/N ratio and uncertainties in observation and model simulations. Also, models still have difficulties in simulating extreme daily precipitation directly comparable with those observed at the station level, which has been addressed to some extent by Min et al. (2011) by independently transforming annual precipitation extremes in models and observations onto a dimensionless scale that may be more comparable between the two. Detection of anthropogenic influence on smaller spatial scales is more difficult due to the increased level of noise and uncertainties and confounding factors on local scales. Fowler and Wilby (2010) suggested that there may have only been a 50% likelihood of detecting anthropogenic influence on UK extreme precipitation in winter at that time, and a very small likelihood of detecting it in other seasons.

Given the evidence of anthropogenic influence on various aspects of the global hydrological cycle that implies that extreme precipitation would be expected to have increased and some limited direct evidence of anthropogenic influence on extreme precipitation, but given also the difficulties in simulating extreme precipitation by climate models and limited observational coverage, we assess, consistent with SREX (Seneviratne et al., 2012) that there is *medium confidence* that anthropogenic forcing has contributed to a global scale intensification of heavy precipitation over the second half of the 20th century in land regions where observational coverage is sufficient for assessment.

10.6.1.3 Drought

AR4 concluded that that an increased risk of drought was *more likely than not* due to anthropogenic forcing during the second half of the

20th century. This assessment was based on one detection study that identified an anthropogenic fingerprint in a global Palmer Drought Severity Index (PDSI) data set (Burke et al., 2006) and studies of some regions which indicated that droughts in those regions were linked to SST changes or to a circulation response to anthropogenic forcing. SREX (Seneviratne et al., 2012) assessed that there was *medium confidence* that anthropogenic influence has contributed to some changes in the drought patterns observed in the second half of the 20th century based on attributed impact of anthropogenic forcing on precipitation and temperature changes, and that there was *low confidence* in the assessment of changes in drought at the level of single regions.

Drought is a complex phenomenon that is affected by precipitation predominantly, as well as by other climate variables including temperature, wind speed and solar radiation (e.g., Seneviratne, 2012; Sheffield et al., 2012). It is also affected by non-atmospheric conditions such as antecedent soil moisture and land surface conditions. Trends in two important drought-related climate variables (precipitation and temperature) are consistent with the expected responses to anthropogenic forcing over the globe. However, there is large uncertainty in observed changes in drought (Section 2.6.2.3) and its attribution to causes globally. The evidence for changes in soil moisture indices and drought indices over the period since 1950 globally is conflicting (Hoerling et al., 2012; Sheffield et al., 2012; Dai, 2013), possibly due to the examination of different time periods, different forcing fields used to drive land surface models and uncertainties in land surface models (Pitman et al., 2009; Seneviratne et al., 2010; Sheffield et al., 2012). In a recent study, Sheffield et al. (2012) identify the representation of potential evaporation as solely dependent on temperature (using the Thornthwaite-based formulation) as a possible explanation for their finding that PDSI-based estimates might overestimate historical drought trends. This stands in partial contradiction to previous assessments suggesting that using a more sophisticated formulation (Penman-Monteith) for potential evaporation did not affect the results of respective PDSI trends (Dai, 2011; van der Schrier et al., 2011). Sheffield et al. (2012) argue that issues with the treatment of spurious trends in atmospheric forcing data sets and/or the choice of calibration periods explain these conflicting results. These conflicting results point out the challenges in quantitatively defining and detecting long-term changes in a multivariable phenomenon such as drought.

Recent long-term droughts in western North America cannot definitively be shown to lie outside the very large envelope of natural precipitation variability in this region (Cayan et al., 2010; Seager et al., 2010), particularly given new evidence of the history of high-magnitude natural drought and pluvial episodes suggested by palaeoclimatic reconstructions (see Chapter 5). Low-frequency tropical ocean temperature anomalies in all ocean basins appear to force circulation changes that promote regional drought (Hoerling and Kumar, 2003; Seager et al., 2005; Dai, 2011). Uniform increases in SST are not particularly effective in this regard (Schubert et al., 2009; Hoerling et al., 2012). Therefore, the reliable separation of natural variability and forced climate change will require simulations that accurately reproduce changes in large-scale SST gradients at all time scales.

In summary, assessment of new observational evidence, in conjunction with updated simulations of natural and forced climate variability, indicates that the AR4 conclusions regarding global increasing trends in droughts since the 1970s should be tempered. There is not enough evidence to support *medium* or *high confidence* of attribution of increasing trends to anthropogenic forcings as a result of observational uncertainties and variable results from region to region (Section 2.6.2.3). Combined with difficulties described above in distinguishing decadal scale variability in drought from long-term climate change we conclude consistent with SREX that there is *low confidence* in detection and attribution of changes in drought over global land areas since the mid-20th century.

10.6.1.4 Extratropical Cyclones

AR4 concluded that an anthropogenic influence on extratropical cyclones was not formally detected, owing to large internal variability and problems due to changes in observing systems. Although there is evidence that there has been a poleward shift in the storm tracks (see Section 2.6.4), various causal factors have been cited including oceanic heating (Butler et al., 2010) and changes in large-scale circulation due to effects of external forcings (Section 10.3.3). Increases in mid-latitude SST gradients generally lead to stronger storm tracks that are shifted poleward and increases in subtropical SST gradients may lead to storm tracks shifting towards the equator (Brayshaw et al., 2008; Semmler et al., 2008; Kodama and Iwasaki, 2009; Graff and LaCasce, 2012). However, changes in storm-track intensity are much more complicated, as they are sensitive to the competing effects of changes in temperature gradients and static stability at different levels and are thus not linked to GMST in a simple way (Ulbrich et al., 2009; O'Gorman, 2010). Overall global average cyclone activity is expected to change little under moderate GHG forcing (O'Gorman and Schneider, 2008; Ulbrich et al., 2009; Bengtsson and Hodges, 2011), although in one study, human influence has been detected in geostrophic wind energy and ocean wave heights derived from sea level pressure data (Wang et al., 2009b).

10.6.1.5 Tropical Cyclones

AR4 concluded that 'anthropogenic factors *more likely than not* have contributed to an increase in tropical cyclone intensity' (Hegerl et al., 2007b). Evidence that supports this assessment was the strong correlation between the Power Dissipation Index (PDI, an index of the destructiveness of tropical cyclones) and tropical Atlantic SSTs (Emanuel, 2005; Elsner, 2006) and the association between Atlantic warming and the increase in GMST (Mann and Emanuel, 2006; Trenberth and Shea, 2006). Observations suggest an increase globally in the intensities of the strongest tropical cyclones (Elsner et al., 2008) but it is difficult to attribute such changes to particular causes (Knutson et al., 2010). The US Climate Change Science Program (CCSP; Kunkel et al., 2008) discussed human contributions to recent hurricane activity based on a two-step attribution approach. They concluded merely that it is very likely (Knutson et al., 2010) that human-induced increase in GHGs has contributed to the increase in SSTs in the hurricane formation regions and that over the past 50 years there has been a strong statistical connection between tropical Atlantic SSTs and Atlantic hurricane activity as measured by the PDI. Knutson et al. (2010), assessed that '…it remains uncertain whether past changes in tropical cyclone activity have exceeded the variability expected from natural causes.' Senevi-

ratne et al. (2012) concurred with this finding. Section 14.6.1 gives a detailed account of past and future changes in tropical cyclones. This section assesses causes of observed changes.

Studies that directly attribute tropical cyclone activity changes to anthropogenic GHG emission are lacking. Among many factors that may affect tropical cyclone activity, tropical SSTs have increased and this increase has been attributed at least in part to anthropogenic forcing (Gillett et al., 2008a). However, there are diverse views on the connection between tropical cyclone activity and SST (see Section 14.6.1 for details). Strong correlation between the PDI and tropical Atlantic SSTs (Emanuel, 2005; Elsner, 2006) would suggest an anthropogenic influence on tropical cyclone activity. However, recent studies also suggest that regional potential intensity correlates with the difference between regional SSTs and spatially averaged SSTs in the tropics (Vecchi and Soden, 2007; Xie et al., 2010; Ramsay and Sobel, 2011) and projections are uncertain on whether the relative SST will increase over the 21st century under GHG forcing (Vecchi et al., 2008; Xie et al., 2010; Villarini and Vecchi, 2012, 2013) . Analyses of CMIP5 simulations suggest that while PDI over the North Atlantic is projected to increase towards late 21st century no detectable change in PDI should be present in the 20th century (Villarini and Vecchi, 2013) . On the other hand, Emanuel et al. (2013) point out that while GCM hindcasts indeed predict little change over the 20th century, downscaling driving by reanalysis data that incorporate historical observations are in much better accord with observations and do indicate a late 20th century increase.

Some recent studies suggest that the reduction in the aerosol forcing (both anthropogenic and natural) over the Atlantic since the 1970s may have contributed to the increase in tropical cyclone activity in the region (see Section 14.6.1 for details), and similarly that aerosols may have acted to reduce tropical cyclone activity in the Atlantic in earlier years when aerosol forcing was increasing (Villarini and Vecchi, 2013). However, there are different views on the relative contribution of aerosols and decadal natural variability of the climate system to the observed changes in Atlantic tropical cyclone activity among these studies. Some studies indicate that aerosol changes have been the main driver (Mann and Emanuel, 2006; Evan et al., 2009; Booth et al., 2012; Villarini and Vecchi, 2012, 2013). Other studies infer the influence of natural variability to be as large as or larger than that from aerosols (Zhang and Delworth, 2009; Villarini and Vecchi, 2012, 2013).

Globally, there is *low confidence* in any long-term increases in tropical cyclone activity (Section 2.6.3) and we assess that there is *low confidence* in attributing global changes to any particular cause. In the North Atlantic region there is *medium confidence* that a reduction in aerosol forcing over the North Atlantic has contributed at least in part to the observed increase in tropical cyclone activity since the 1970s. There remains substantial disagreement on the relative importance of internal variability, GHG forcing and aerosols for this observed trend. It remains uncertain whether past changes in tropical cyclone activity are outside the range of natural internal variability.

10.6.2 Attribution of Weather and Climate Events

Since many of the impacts of climate change are likely to manifest themselves through extreme weather, there is increasing interest in quantifying the role of human and other external influences on climate in specific weather events. This presents particular challenges for both science and the communication of results. It has so far been attempted for a relatively small number of specific events (e.g., Stott et al., 2004; Pall et al., 2011) although Peterson et al. (2012) attempt, for the first time, a coordinated assessment to place different high-impact weather events of the previous year in a climate perspective. In this assessment, selected studies are used to illustrate the essential principles of event attribution: see Stott et al. (2013) for a more exhaustive review.

Two distinct ways have emerged of framing the question of how an external climate driver like increased GHG levels may have contributed to an observed weather event. First, the 'attributable risk' approach considers the event as a whole, and asks how the external driver may have increased or decreased the probability of occurrence of an event of comparable magnitude. Second, the 'attributable magnitude' approach considers how different external factors contributed to the event or, more specifically, how the external driver may have increased the magnitude of an event of comparable occurrence probability. Hoerling et al. (2013) uses both methods to infer changes in magnitude and likelihood of the 2011 Texas heat wave.

Quantifying the absolute risk or probability of an extreme weather event in the absence of human influence on climate is particularly challenging. Many of the most extreme events occur because a self-reinforcing process that occurs only under extreme conditions amplifies an initial anomaly (e.g., Fischer et al., 2007). Hence the probability of occurrence of such events cannot, in general, be estimated simply by extrapolating from the distribution of less extreme events that are sampled in the historical record. Proxy records of pre-industrial climate generally do not resolve high-frequency weather, so inferring changes in probabilities requires a combination of hard-to-test distributional assumptions and extreme value theory. Quantifying absolute probabilities with climate models is also difficult because of known biases in their simulation of extreme events. Hence, with only a couple of exceptions (e.g., Hansen et al., 2012), studies have focussed on how risks have changed or how different factors have contributed to an observed event, rather than claiming that the absolute probability of occurrence of that event would have been extremely low in the absence of human influence on climate.

Even without considering absolute probabilities, there remain considerable uncertainties in quantifying changes in probabilities. The assessment of such changes will depend on the selected indicator, time period and spatial scale on which the event is analysed, and the way in which the event-attribution question is framed can substantially affect apparent conclusions . If an event occurs in the tail of the distribution, then a small shift in the distribution as a whole can result in a large increase in the probability of an event of a given magnitude: hence it is possible for the same event to be both 'mostly natural' in terms of attributable magnitude (if the shift in the distribution due to human influence is small compared to the anomaly in the natural variability that was the primary cause) and 'mostly anthropogenic' in terms of

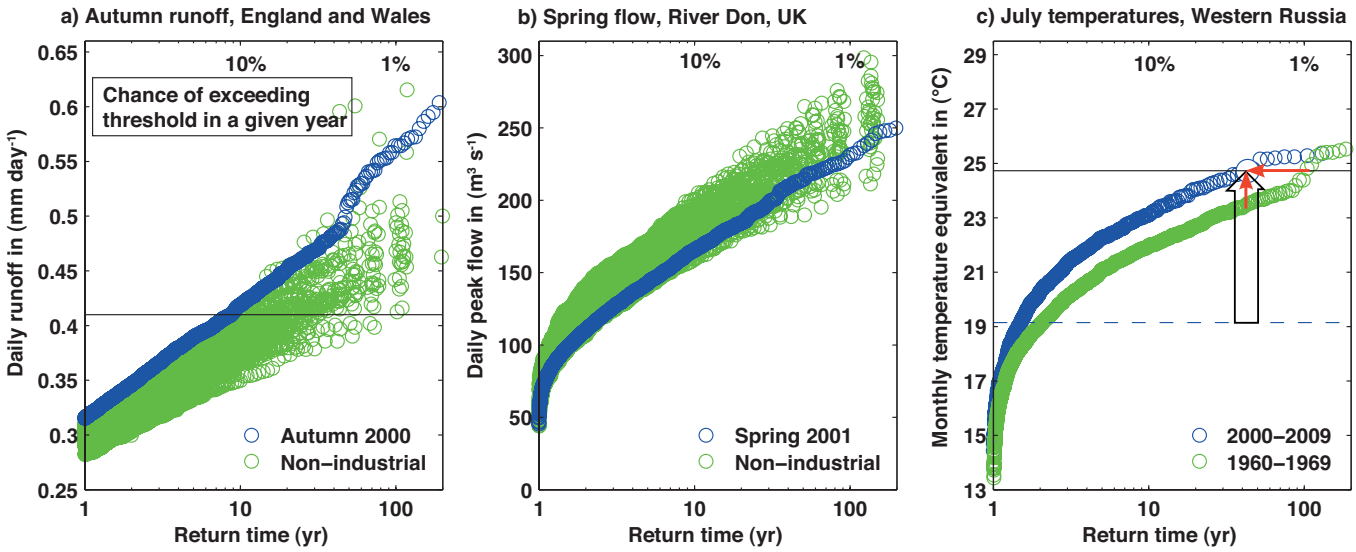

Figure 10.18 | Return times for precipitation-induced floods aggregated over England and Wales for (a) conditions corresponding to September to November 2000 with boundary conditions as observed (blue) and under a range of simulations of the conditions that would have obtained in the absence of anthropogenic greenhouse warming over the 20th century (green) with different AOGCMs used to define the greenhouse signal, black horizontal line corresponds to the threshold exceeded in autumn 2000 (from Pall et al., 2011); (b) corresponding to January to March 2001 with boundary conditions as observed (blue) and under a range of simulations of the condition that would have obtained in the absence of anthropogenic greenhouse warming over the 20th century (green) adapted from Kay et al. (2011a); (c) return periods of temperature-geopotential height conditions in the model simulations for the 1960s (green) and the 2000s (blue). The vertical black arrow shows the anomaly of the 2010 Russian heat wave (black horizontal line) compared to the July mean temperatures of the 1960s (dashed line). The vertical red arrow gives the increase in temperature for the event whereas the horizontal red arrow shows the change in the return period (from Otto et al., 2012).

attributable risk (if human influence has increased its probability of occurrence by more than a factor of 2). These issues are discussed further using the example of the 2010 Russian heat wave below.

The majority of studies have focussed on quantifying attributable risk. Formally, risk is a function of both hazard and vulnerability (IPCC, 2012), although most studies attempting to quantify risk in the context of extreme weather do not explicitly use this definition, which is discussed further in Chapter 19 of WGII, but use the term as a shorthand for the probability of the occurrence of an event of a given magnitude. Any assessment of change in risk depends on an assumption of 'all other things being equal', including natural drivers of climate change and vulnerability. Given this assumption, the change in hazard is proportional to the change in risk, so we will follow the published literature and continue to refer to Fraction Attributable Risk, defined as FAR = 1 – P0/P1, P0 being the probability of an event occurring in the absence of human influence on climate, and P1 the corresponding probability in a world in which human influence is included. FAR is thus the fraction of the risk that is attributable to human influence (or, potentially, any other external driver of climate change) and does not require knowledge of absolute values of P0 and P1, only their ratio.

For individual events with return times greater than the time scale over which the signal of human influence is emerging (30 to 50 years, meaning P0 and P1 less than 2 to 3% in any given year), it is impossible to observe a change in occurrence frequency directly because of the shortness of the observed record, so attribution is necessarily a multi-step procedure. Either a trend in occurrence frequency of more frequent events is attributed to human influence and a statistical model is then used to extrapolate to the implications for P0 and P1; or an attributable trend is identified in some other variable, such as surface temperature, and a physically based weather model is used to assess the implications for extreme weather risk. Neither approach is free of assumptions: no atmospheric model is perfect, but statistical extrapolation may also be misleading for reasons given above.

Pall et al. (2011) provide an example of multi-step assessment of attributable risk using a physically based model, applied to the floods that occurred in the UK in the autumn of 2000, the wettest autumn to have occurred in England and Wales since records began. To assess the contribution of the anthropogenic increase in GHGs to the risk of these floods, a several thousand member ensemble of atmospheric models with realistic atmospheric composition, SST and sea ice boundary conditions imposed was compared with a second ensemble with composition and surface temperatures and sea ice boundary conditions modified to simulate conditions that would have occurred had there been no anthropogenic increase in GHGs since 1900. Simulated daily precipitation from these two ensembles was fed into an empirical rainfall-runoff model and daily England and Wales runoff used as a proxy for flood risk. Results (Figure 10.18a) show that including the influence of anthropogenic greenhouse warming increases flood risk at the threshold relevant to autumn 2000 by around a factor of two in the majority of cases, but with a broad range of uncertainty: in 10% of cases the increase in risk is less than 20%.

Kay et al. (2011a), analysing the same ensembles but using a more sophisticated hydrological model found a reduction in the risk of snow melt–induced flooding in the spring season (Figure 10.18b) which, aggregated over the entire year, largely compensated for the increased risk of precipitation-induced flooding in autumn. This illustrates an

important general point: even if a particular flood event may have been made more likely by human influence on climate, there is no certainty that all kinds of flood events in that location, country or region have been made more likely.

Rahmstorf and Coumou (2011) provide an example of an empirical approach to the estimation of attributable risk applied to the 2010 Russian heat wave. They fit a nonlinear trend to central Russian temperatures and show that the warming that has occurred in this region since the 1960s has increased the risk of a heat wave of the magnitude observed in 2010 by around a factor of 5, corresponding to an FAR of 0.8. They do not address what has caused the trend since 1960, although they note that other studies have attributed most of the large-scale warming over this period to the anthropogenic increase in GHG concentrations.

Dole et al. (2011) take a different approach to the 2010 Russian heat wave, focussing on attributable magnitude, analysing contributions from various external factors, and conclude that this event was 'mainly natural in origin'. First, observations show no evidence of a trend in occurrence frequency of hot Julys in western Russia, and despite the warming that has occurred since the 1960s, mean July temperatures in that region actually display a (statistically insignificant) cooling trend over the century as a whole, in contrast to the case for central and southern European summer temperatures (Stott et al., 2004). Members of the CMIP3 multi-model ensemble likewise show no evidence of a trend towards warming summers in central Russia. Second, Dole et al. (2011) note that the 2010 Russian event was associated with a strong blocking atmospheric flow anomaly, and even the complete 2010 boundary conditions are insufficient to increase the probability of a prolonged blocking event in this region, in contrast again to the situation in Europe in 2003. This anomaly in the large-scale atmospheric flow led to low-pressure systems being redirected around the blocking over Russia causing severe flooding in Pakistan which could so far not be attributed to anthropogenic causes (van Oldenborgh et al., 2012), highlighting that a global perspective is necessary to unravel the different factors influencing individual extreme events (Trenberth and Fasullo, 2012).

Otto et al. (2012) argue that it is possible to reconcile the results of Rahmstorf and Coumou (2011) with those of Dole et al. (2011) by relating the attributable risk and attributable magnitude approaches to framing the event attribution question. This is illustrated in Figure 10.18c, which shows return times of July temperatures in western Russia in a large ensemble of atmospheric model simulations for the 1960s (in green) and 2000s (in blue). The threshold exceeded in 2010 is shown by the solid horizontal line which is almost 6°C above 1960s mean July temperatures, shown by the dashed line. The difference between the green and blue lines could be characterized as a 1.5°C increase in the magnitude of a 30-year event (the vertical red arrow, which is substantially smaller than the size of the anomaly itself, supporting the assertion that the event was 'mainly natural' in terms of attributable magnitude. Alternatively, it could be characterized as a threefold increase in the risk of the 2010 threshold being exceeded, supporting the assertion that risk of the event occurring was mainly attributable to the external trend, consistent with Rahmstorf and Coumou (2011). Rupp et al. (2012) and Hoerling et al. (2013) reach similar conclusions about the 2011 Texas heat wave, both noting the importance of La Niña conditions in the Pacific, with anthropogenic warming making a relatively small contribution to the magnitude of the event, but a more substantial contribution to the risk of temperatures exceeding a high threshold. This shows that the quantification of attributable risks and and changes in magnitude are affected by modelling error (e.g., Visser and Petersen, 2012) as they depend on the atmospheric model's ability to simulate the observed anomalies in the general circulation (Chapter 9).

Because much of the magnitude of these two heat waves is attributable to atmospheric flow anomalies, any evidence of a causal link between rising GHGs and the occurrence or persistence of flow anomalies such as blocking would have a very substantial impact on attribution claims. Pall et al. (2011) argue that, although flow anomalies played a substantial role in the autumn 2000 floods in the UK, thermodynamic mechanisms were primarily responsible for the change in risk between their ensembles. Regardless of whether the statistics of flow regimes themselves have changed, observed temperatures in recent years in Europe are distinctly warmer than would be expected for analogous atmospheric flow regimes in the past, affecting both warm and cold extremes (Yiou et al., 2007; Cattiaux et al., 2010).

In summary, increasing numbers of studies are finding that the probability of occurrence of events associated with extremely high temperatures has increased substantially due to the large-scale warming since the mid-20th century. Because most of this large-scale warming is *very likely* due to the increase in atmospheric GHG concentrations, it is possible to attribute, via a multi-step procedure, some of the increase in probability of these regional events to human influence on climate. Such an increase in probability is consistent with the implications of single-step attribution studies looking at the overall implications of increasing mean temperatures for the probabilities of exceeding temperature thresholds in some regions. We conclude that it is *likely* that human influence has substantially increased the probability of occurrence of heat waves in some locations. It is expected that attributable risks for extreme precipitation events are generally smaller and more uncertain, consistent with the findings in Kay et al. (2011a) and Pall et al. (2011). The science of event attribution is still confined to case studies, often using a single model, and typically focussing on high-impact events for which the issue of human influence has already arisen. While the increasing risk of heat waves measured as the occurrence of a previous temperature record being exceeded can simply be explained by natural variability superimposed by globally increasing temperature, conclusions for holistic events including general circulation patterns are specific to the events that have been considered so far and rely on the representation of relevant processes in the model.

Anthropogenic warming remains a relatively small contributor to the overall magnitude of any individual short-term event because its magnitude is small relative to natural random weather variability on short time scales (Dole et al., 2011; Hoerling et al., 2013). Because of this random variability, weather events continue to occur that have been made less likely by human influence on climate, such as extreme winter cold events (Massey et al., 2012), or whose probability of occurrence has not been significantly affected either way. Quantifying how different external factors contribute to current risks, and how risks are

changing, is possible with much higher confidence than quantifying absolute risk. Biases in climate models, uncertainty in the probability distribution of the most extreme events and the ambiguity of paleoclimatic records for short-term events mean that it is not yet possible to quantify the absolute probability of occurrence of any observed weather event in a hypothetical pristine climate. At present, therefore, the evidence does not support the claim that we are observing weather events that would, individually, have been *extremely unlikely* in the absence of human-induced climate change, although observed trends in the concurrence of large numbers of events (see Section 10.6.1) may be more easily attributable to external factors. The most important development since AR4 is an emerging consensus that the role of external drivers of climate change in specific extreme weather events, including events that might have occurred in a pre-industrial climate, can be quantified using a probabilistic approach.

10.7 Multi-century to Millennia Perspective

Evaluating the causes of climate change before the 20th century is important to test and improve our understanding of the role of internal and forced natural climate variability for the recent past. This section draws on assessment of temperature reconstructions of climate change over the past millennium and their uncertainty in Chapter 5 (Table 5.A.1; Sections 5.3.5 and 5.5.1 for regional records), and on comparisons of models and data over the pre-instrumental period in Chapters 5 and 9 (Sections 5.3.5, 5.5.1 and 9.5.3), and focuses on the evidence for the contribution by radiatively forced climate change to reconstructions and early instrumental records. In addition, the residual variability that is not explained by forcing from palaeoclimatic records provides a useful comparison to estimates of climate model internal variability. The model dependence of estimates of internal variability is an important uncertainty in detection and attribution results.

The inputs for detection and attribution studies for periods covered by indirect, or proxy, data are affected by more uncertainty than those from the instrumental period (see Chapter 5), owing to the sparse data coverage, particularly further back in time, and uncertainty in the link between proxy data and, for example, temperature. Records of past radiative influences on climate are also uncertain (Section 5.2; see Schmidt et al., 2011; Schmidt et al., 2012). For the preindustrial part of the last millennium changes in solar, volcanic, GHG forcing, and land use change, along with a small orbital forcing are potentially important external drivers of climate change. Estimates of solar forcing (Figure 5.1a; Box 10.2) are uncertain, particularly in their amplitude, as well as in modelling, for example, of the influence of solar forcing on atmospheric circulation involving stratospheric dynamics (see Box 10.2; Gray et al., 2010). Estimates of past volcanism are reasonably well established in their timing, but the magnitude of the RF of individual eruptions is uncertain (Figure 5.1a). It is possible that large eruptions had a more moderated climate effect than simulated by many climate models due to faster fallout associated with larger particle size (Timmreck et al., 2009), or increased amounts of injected water vapour (Joshi and Jones, 2009). Reconstructed changes in land cover and its effect on climate are also uncertain (Kaplan et al., 2009; Pongratz et al., 2009). Forcing of WMGHGs shows only very subtle variations over the last millennium up to 1750. This includes a small drop and partial recovery in the 17th century (Section 6.2.3, Figure 6.7), followed by increases in GHG concentrations with industrialization since the middle of the 18th century (middle of the 19th century for N_2O, Figure 6.11).

When interpreting reconstructions of past climate change with the help of climate models driven with estimates of past forcing, it helps that the uncertainties in reconstructions and forcing are independent from each other. Thus, uncertainties in forcing and reconstructions combined should lead to less, rather than more similarity between fingerprints of forced climate change and reconstructions, making it improbable that the response to external drivers is spuriously detected. However, this is the case only if all relevant forcings and their uncertainties are considered, reducing the risk of misattribution due to spurious correlations between external forcings, and if the data are homogeneous and statistical tests properly applied (e.g., Legras et al., 2010). Hence this section focuses on work that considers all relevant forcings simultaneously.

10.7.1 Causes of Change in Large-Scale Temperature over the Past Millennium

Despite the uncertainties in reconstructions of past NH mean temperatures, there are well-defined climatic episodes in the last millennium that can be robustly identified (Chapter 5, see also Figure 10.19). Chapter 5 concludes that in response to solar, volcanic and anthropogenic RFs, climate models simulate temperature changes in the NH which are generally consistent in magnitude and timing with reconstructions, within their broad uncertainty ranges (Section 5.3.5).

10.7.1.1 Role of External Forcing in the Last Millennium

The AR4 concluded that 'A substantial fraction of the reconstructed NH inter-decadal temperature variability of the seven centuries prior to 1950 is *very likely* attributable to natural external forcing'. The literature since the AR4, and the availability of more simulations of the last millennium with more complete forcing (see Schmidt et al., 2012), including solar, volcanic and GHG influences, and generally also land use change and orbital forcing) and more sophisticated models, to a much larger extent coupled climate or coupled ESMs (Chapter 9), some of them with interactive carbon cycle, strengthens these conclusions.

Most reconstructions show correlations with external forcing that are similar to those found between pre-Paleoclimate Modelling Intercomparison Project Phase 3 (PMIP3) simulations of the last millennium and forcing, suggesting an influence by external forcing (Fernández-Donado et al., 2013). From a global scale average of new regional reconstructions, Past Global Changes 2k (PAGES 2k) Consortium (2013) find that periods with strong volcanic and solar forcing combined occurring over the last millennium show significantly cooler conditions than randomly selected periods from the last two millennia. Detection analyses based on PMIP3 and CMIP5 model simulations for the years from 850 to 1950 and also from 850 to 1850 find that the fingerprint of external forcing is detectable in all reconstructions of NH mean temperature considered (Schurer et al., 2013; see Figure 10.19), but only in about half the cases considered does detection also occur prior to 1400. The authors find a smaller response to forcing in reconstructions than simulated, but this discrepancy is consistent with

uncertainties in forcing or proxy response to it, particularly associated with volcanism. The discrepancy is reduced when using more strongly smoothed data or omitting major volcanic eruptions from the analysis. The level of agreement between fingerprints from multiple models in response to forcing and reconstructions decreases earlier in time, and the forced signal is detected only in about half the cases considered when analysing the period 851 to 1401. This may be partly due to weaker forcing and larger forcing uncertainty early in the millennium and partly due to increased uncertainty in reconstructions. Detection results indicate a contribution by external drivers to the warm conditions in the 11th to 12th century, but cannot explain the warmth around the 10th century in some of the reconstructions (Figure 10.19). This detection of a role of external forcing extends work reported in AR4 back into to the 9th century CE.

Detection and attribution studies support results from modelling studies that infer a strong role of external forcing in the cooling of NH temperatures during the Little Ice Age (LIA; see Chapter 5 and Glossary). Both model simulations (Jungclaus et al., 2010) and results from detection and attribution studies (Hegerl et al., 2007a; Schurer et al., 2013) suggest that a small drop in GHG concentrations may have contributed to the cool conditions during the 16th and 17th centuries. Note, however, that centennial variations of GHG during the late Holocene are very small relative to their increases since pre-industrial times (Section 6.2.3). The role of solar forcing is less clear except for decreased agreement if using very large solar forcing (e.g., Ammann et al., 2007; Feulner, 2011). Palastanga et al. (2011) demonstrate that neither a slowdown of the thermohaline circulation nor a persistently negative NAO alone can explain the reconstructed temperature pattern over Europe during the periods 1675–1715 and 1790–1820.

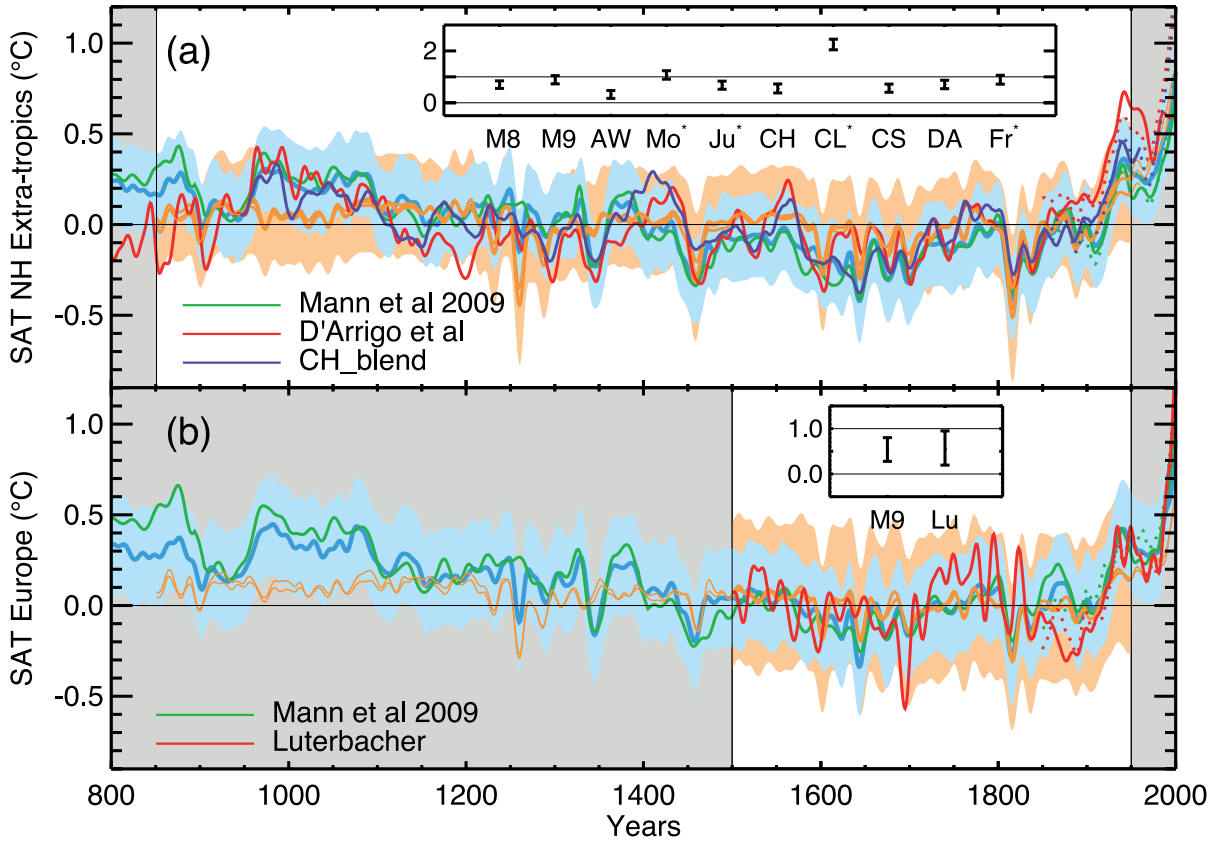

Figure 10.19 | The top panel compares the mean annual Northern Hemisphere (NH) surface air temperature from a multi-model ensemble to several NH temperature reconstructions. These reconstructions are: CH-blend from Hegerl et al. (2007a) in purple, which is a reconstruction of 30°N to 90°N land only (Mann et al., 2009), plotted for the region 30°N to 90°N land and sea (green) and D'Arrigo et al. (2006) in red, which is a reconstruction of 20°N to 90°N land only. The dotted coloured lines show the corresponding instrumental data. The multi-model mean for the reconstructed domain is scaled to fit each reconstruction in turn, using a total least squares (TLS) method. The best estimate of the detected forced signal is shown in orange (as an individual line for each reconstruction; lines overlap closely) with light orange shading indicating the range expected if accounting for internal variability. The best fit scaling values for each reconstruction are given in the insert as well as the detection results for six other reconstructions (M8; M9 (Mann et al., 2008, 2009); AW (Ammann and Wahl, 2007); Mo (Moberg et al., 2005); Ju (Juckes et al., 2007); CH (Hegerl et al., 2007a); CL (Christiansen and Ljungqvist, 2011) and inverse regressed onto the instrumental record CS; DA (D'Arrigo et al., 2006); Fr (Frank et al., 2007). An asterisk next to the reconstruction name indicates that the residuals (over the more robustly reconstructed period 1401–1950) are inconsistent with the internal variability generated by the combined control simulations of all climate models investigated (for details see Schurer et al., 2013). The ensemble average of a data-assimilation simulation (Goosse et al., 2012b) is plotted in blue, for the region 30°N to 90°N land and sea, with the error range shown in light blue shading. The bottom panel is similar to the top panel, but showing the European region, following Hegerl et al. (2011a) but using the simulations and method in Schurer et al. (2013). The detection analysis is performed for the period 1500–1950 for two reconstructions: Luterbacher et al. (2004)(representing the region 35°N to 70°N, 25°W to 40°E, "land only, labelled 'Lu' in the insert") shown in red, and Mann et al. (2009) (averaged over the region 25°N to 65°N, 0° to 60°E, land and sea, labelled 'M9' in the insert), shown in green. As in the top panel, best fit estimates are shown in dark orange with uncertainty range due to internal variability shown in light orange. The data assimilation from Goosse et al. (2012a), constrained by the Mann et al. (2009) reconstruction is shown in blue, with error range in light blue. All data are shown with respect to the mean of the period covered by the white part of the figure (850–1950 for the NH, 1500–1950 for European mean data).

Data assimilation studies support the conclusion that external forcing, together with internal climate variability, provides a consistent explanation of climate change over the last millennium. Goosse et al. (2010, 2012a, 2012b) select, from a very large ensemble with an EMIC, the individual simulations that are closest to the spatial reconstructions of temperature between 30°N and 60°N by Mann et al. (2009) accounting for reconstruction uncertainties. The method also varies the external forcing within uncertainties, determining a combined realization of the forced response and internal variability that best matches the data. Results (Figure 10.19) show that simulations reproduce the target reconstruction within the uncertainty range, increasing confidence in the consistency of the reconstruction and the forcing. The results suggest that long-term circulation anomalies may help to explain the hemispheric warmth early in the millennium, although results vary dependent on input parameters of the method.

10.7.1.2 Role of Individual Forcings

Volcanic forcing shows a detectable influence on large-scale temperature (see AR4; Chapter 5), and volcanic forcing plays an important role in explaining past cool episodes, for example, in the late 17th and early 19th centuries (see Chapter 5 and 9; Hegerl et al., 2007b; Jungclaus et al., 2010; Miller et al., 2012) . Schurer et al. (2013) separately detect the response to GHG variations between 1400 and 1900 in most NH reconstructions considered, and that of solar and volcanic forcing combined in all reconstructions considered.

Even the multi-century perspective makes it difficult to distinguish century-scale variations in NH temperature due to solar forcing alone from the response to other forcings, due to the few degrees of freedom constraining this forcing (see Box 10.2). Hegerl et al. (2003, 2007a) found solar forcing detectable in some cases. Simulations with higher than best guess solar forcing may reproduce the warm period around 1000 more closely, but the peak warming occurs about a century earlier in reconstructions than in solar forcing and with it model simulations (Jungclaus et al., 2010; Figure 5.8; Fernández-Donado et al., 2013). Even if solar forcing were on the high end of estimates for the last millennium, it would not be able to explain the recent warming according both to model simulations (Ammann et al., 2007; Tett et al., 2007; Feulner, 2011) and detection and attribution approaches that scale the temporal fingerprint of solar forcing to best match the data (Hegerl et al., 2007a; Schurer et al., 2013; Figure 10.19). Some studies suggest that particularly for millennial and multi-millenial time scales orbital forcing may be important globally (Marcott et al., 2013) and for high-latitude trends (Kaufman et al., 2009) based on a comparison of the correspondence between long-term Arctic cooling in models and data though the last millennium up to about 1750 (see also PAGES 2k Consortium, 2013).

10.7.1.3 Estimates of Internal Climate Variability

The interdecadal and longer-term variability in large-scale temperatures in climate model simulations with and without past external forcing is quite different (Tett et al., 2007; Jungclaus et al., 2010), consistent with the finding that a large fraction of temperature variance in the last millennium has been externally driven. The residual variability in past climate that is not explained by changes in RF provides an estimate of internal variability for NH mean temperature that is not directly derived from climate model simulation. This residual variability is somewhat larger than control simulation variability for some reconstructions if the comparison is extended to the full period since 850 CE (Schurer et al., 2013), However, when extracting 50- and 60-year trends from this residual variability, the distribution of these trends is similar to the multi-model control simulation ensemble used in Schurer et al. (2013). In all cases considered, the most recent 50-and 60-year trend from instrumental data is far outside the range of any 50-year trend in residuals from reconstructions of NH mean temperature of the past millennium.

10.7.2 Changes of Past Regional Temperature

Several reconstructions of European regional temperature variability are available (Section 5.5). While Bengtsson et al. (2006) emphasized the role of internal variability in pre-industrial European climate as reconstructed by Luterbacher et al. (2004), Hegerl et al. (2011a) find a detectable response to external forcing in summer temperatures in the period 1500–1900, for winter temperatures during 1500–1950 and 1500–2000; and throughout the record for spring. The fingerprint of the forced response shows coherent time evolution between models and reconstructed temperatures over the entire analysed period (compare to annual results in Figure 10.19, using a larger multi-model ensemble). This suggests that the cold European winter conditions in the late 17th and early 19th century and the warming in between were at least partly externally driven.

Data assimilation results focussing on the European sector suggests that the explanation of forced response combined with internal variability is self-consistent (Goosse et al., 2012a, Figure 10.19). The assimilated simulations reproduce the warmth of the MCA better than the forced only simulations do. The response to individual forcings is difficult to distinguish from each other in noisier regional reconstructions. An epoch analysis of years immediately following strong, largely tropical, volcanic eruptions shows that European summers show detectable fingerprints of volcanic response , while winters show a noisy response of warming in northern Europe and cooling in southern Europe (Hegerl et al., 2011a). Landrum et al. (2013) suggest similar volcanic responses for North America, with warming in the north of the continent and cooling in the south. There is also evidence for a decrease in SSTs following tropical volcanic forcing in tropical reconstructions over the past 450 years (D'Arrigo et al., 2009). There is also substantial literature suggesting solar influences on regional climate reconstructions, possibly due to circulation changes, for example, changes in Northern Annular Modes (e.g., Kobashi et al., 2013; see Box 10.2).

10.7.3 Summary: Lessons from the Past

Detection and attribution studies strengthen results from AR4 that external forcing contributed to past climate variability and change prior to the 20th century. Ocean–Atmosphere General Circulation Models (OAGCMs) simulate similar changes on hemispheric and annual scales as those by simpler models used earlier, and enable detection of regional and seasonal changes. Results suggest that volcanic forcing and GHG forcing in particular are important for explaining past changes in NH temperatures. Results from data assimilation runs confirm

that the combination of internal variability and external forcing provides a consistent explanation of the last millennium and suggest that changes in circulation may have further contributed to climate anomalies. The role of external forcing extends to regional records, for example, European seasonal temperatures. In summary, it is *very unlikely* that NH temperature variations from 1400 to 1850 can be explained by internal variability alone. There is *medium confidence* that external forcing contributed to NH temperature variability from 850 to 1400. There is *medium confidence* that external forcing (anthropogenic and natural forcings together) contributed to European temperatures of the last five centuries.

10.8 Implications for Climate System Properties and Projections

Detection and Attribution results can be used to constrain predictions of future climate change (see Chapters 11 and 12) and key climate system properties. These properties include: the Equilibrium Climate Sensitivity (ECS), which determines the long-term equilibrium warming response to stable atmospheric composition, but not accounting for vegetation or ice sheet changes (Section 12.5.3; see Box 12.2); the transient climate response (TCR), which is a measure of the magnitude of transient warming while the climate system, particularly the deep ocean, is not in equilibrium; and the transient climate response to cumulative CO_2 emissions (TCRE), which is a measure of the transient warming response to a given mass of CO_2 injected into the atmosphere, and combines information on both the carbon cycle and climate response. TCR is more tightly constrained by the observations of transient warming than ECS. The observational constraints on TCR, ECS and TCRE assessed here focus on information provided by recent observed climate change, complementing analysis of feedbacks and climate modelling information, which are assessed in Chapter 9. The assessment in this chapter also incorporates observational constraints based on palaeoclimatic information, building on Chapter 5, and contributes to the overall synthesis assessment in Chapter 12 (Box 12.2).

Because neither ECS nor TCR is directly observed, any inference about them requires some form of climate model, ranging in complexity from a simple zero-dimensional energy balance box model to OAGCMs (Hegerl and Zwiers, 2011). Constraints on estimates of long-term climate change and equilibrium climate change from recent warming hinge on the rate at which the ocean has taken up heat (Section 3.2), and by the extent to which recent warming has been reduced by cooling from aerosol forcing. Therefore, attempts to estimate climate sensitivity (transient or equilibrium) often also estimate the total aerosol forcing and the rate of ocean heat uptake, which are discussed in Section 10.8.3. The AR4 contained a detailed discussion on estimating quantities relevant for projections, and included an appendix with the relevant estimation methods. Here, we build on this assessment, repeating information and discussion only where necessary to provide context.

10.8.1 Transient Climate Response

The AR4 discussed for the first time estimates of the TCR. TCR was originally defined as the warming at the time of CO_2 doubling (i.e., after 70 years) in a 1% yr^{-1} increasing CO_2 experiment (see Hegerl et al., 2007b), but like ECS, it can also be thought of as a generic property of the climate system that determines the global temperature response ΔT to any gradual increase in RF, ΔF, taking place over an approximately 70-year time scale, normalized by the ratio of the forcing change to the forcing due to doubling CO_2, $F_{2\times CO2}$: TCR = $F_{2\times CO2}\ \Delta T/\Delta F$ (Frame et al., 2006; Gregory and Forster, 2008; Held et al., 2010; Otto et al., 2013). This generic definition of the TCR has also been called the 'Transient Climate Sensitivity' (Held et al., 2010). TCR is related to ECS and the global energy budget as follows: ECS = $F_{2\times CO2}/\alpha$, where α is the sensitivity parameter representing the net increase in energy flux to space per degree of warming given all feedbacks operating on these time scales. Hence, by conservation of energy, ECS = $F_{2\times CO2}\ \Delta T/(\Delta F - \Delta Q)$, where ΔQ is the change in the rate of increase of climate system heat content in response to the forcing ΔF. On these time scales, deep ocean heat exchange affects the surface temperature response as if it were an enhanced radiative damping, introducing a slow, or 'recalcitrant', component of the response which would not be reversed for many decades even if it were possible to return RF to pre-industrial values (Held et al., 2010): hence the difficulty of placing an upper bound on ECS from observed surface warming alone (Forest et al., 2002; Frame et al., 2006). Because ΔQ is always positive at the end of a period of increasing forcing, before the climate system has re-equilibrated, TCR is always less than ECS, and since ΔQ is uncertain, TCR is generally better constrained by observations of recent climate change than ECS.

Because TCR focuses on the short- and medium-term response, constraining TCR with observations is a key step in narrowing estimates of future global temperature change in the relatively short term and under scenarios where forcing continues to increase or peaks and declines (Frame et al., 2006). After stabilization, the ECS eventually becomes the relevant climate system property. Based on observational constraints alone, the AR4 concluded that TCR is *very likely* to be larger than 1°C and *very unlikely* to be greater than 3.5°C (Hegerl et al., 2007b). This supported the overall assessment that the transient climate response is *very unlikely* greater than 3°C and *very likely* greater than 1°C (Meehl et al., 2007a). New estimates of the TCR are now available.

Scaling factors derived from detection and attribution studies (see Section 10.2) express how model responses to GHGs and aerosols need to be scaled to match the observations over the historical period. These scaled responses were used in AR4 to provide probabilistic projections of both TCR and future changes in global temperature in response to these forcings under various scenarios (Allen et al., 2000; Stott and Kettleborough, 2002; Stott et al., 2006, 2008b; Kettleborough et al., 2007; Meehl et al., 2007b; Stott and Forest, 2007). Allen et al. (2000), Frame et al. (2006) and Kettleborough et al. (2007) demonstrate a near linear relationship between 20th century warming, TCR and warming by the mid-21st century as parameters are varied in Energy Balance Models, justifying this approach. Forster et al. (2013) show how the ratio $\Delta T/\Delta F$ does depend on the forcing history, with very rapid increases in forcing giving lower values: hence any inference from past attributable warming to future warming or TCR depends on a model (which may be simple or complex, but ideally physically based) to relate these quantities. Such inferences also depend on forcing estimates and projections. Recent revisions to RF (see Chapter 8) suggest higher net anthropogenic forcing over the 20th century, and hence a smaller estimated

TCR. Stott et al. (2008b) demonstrated that optimal detection analysis of 20th century temperature changes (using HadCM3) are able to exclude the very high and low temperature responses to aerosol forcing. Consequently, projected 21st century warming may be more closely constrained than if the full range of aerosol forcings is used (Andreae et al., 2005). Stott and Forest (2007) demonstrate that projections obtained from such an approach are similar to those obtained by constraining EMIC parameters from observations. Stott et al. (2011), using HadGEM2-ES, and Gillett et al. (2012), using CanESM2, both show that the inclusion of observations between 2000 and 2010 in such an analysis reduces the uncertainties in projected warming in the 21st century, and tends to constrain the maximum projected warming to below that projected using data to 2000 only (Stott et al, 2006). Such an improvement is consistent with prior expectations of how additional data will narrow uncertainties (Stott and Kettleborough, 2002).

TCR estimates have been derived using a variety of methods (Figure 10.20a). Knutti and Tomassini (2008) compare EMIC simulations with 20th century surface and ocean temperatures to derive a probability density function for TCR skewed slightly towards lower values with a 5 to 95% range of 1.1°C to 2.3°C. Libardoni and Forest (2011) take a similar approach with a different EMIC and include atmospheric data and, under a variety of assumptions, obtain 5 to 95% ranges for TCR spanning 0.9°C to 2.4°C. Updating this study to include data to 2004 gives results that are essentially unchanged. Using a single model and observations from 1851 to 2010 Gillett et al. (2012) derive a 5 to 95% range of 1.3°C to 1.8°C and using a single model, but using multiple sets of observations and analysis periods ending in 2010 and beginning in 1910 or earlier, Stott et al. (2011) derive 5 to 95% ranges that were generally between 1°C and 3°C. Both Stott et al. (2011) and Gillett et al. (2012) find that the inclusion of data between 2000 and 2010 helps to constrain the upper bound of TCR. Gillett et al. (2012) find that the inclusion of data prior to 1900 also helps to constrain TCR, though Stott et al. (2011) do not. Gillett et al. (2013) account for a broader range of model and observational uncertainties, in particular addressing the efficacy of non-CO_2 gases, and find a range of 0.9°C to 2.3°C. Several of the estimates of TCR that were cited by Hegerl et al. (2007b) may have underestimated non-CO_2 efficacies relative to the more recent estimates in Forster et al. (2007). Because observationally constrained estimates of TCR are based on the ratio between past attributable warming and past forcing, this could account for a high bias in some of the inputs used for the AR4 TCR estimate.

Held et al. (2010) show that a two-box model originally proposed by Gregory (2000), distinguishing the 'fast' and 'recalcitrant' responses, fits both historical simulations and instantaneous doubled CO_2 simulations of the GFDL coupled model CM2.1. The fast response has a relaxation time of 3 to 5 years, and the historical simulation is almost completely described by this fast component of warming. Padilla et al. (2011) use this simple model to derive an observationally constrained estimate of the TCR of 1.3°C to 2.6°C. Schwartz (2012) uses this two-time scale formulation to obtain TCR estimates ranging from 0.9°C to 1.9°C, the lower values arising from higher estimates of forcing over the 20th century. Otto et al. (2013) update the analysis of Gregory et al. (2002) and Gregory and Forster (2008) using forcing estimates from Forster et al. (2013) to obtain a 5 to 95% range for TCR of 0.9°C to 2.0°C comparing the decade 2000–2009 with the period 1860–1879. They note, however, the danger of overinterpreting a single, possibly anomalous, decade, and report a larger TCR range of 0.7°C to 2.5°C replacing the 2000s with the 40 years 1970–2009.

Tung et al. (2008) examine the response to the 11-year solar cycle using discriminant analysis, and find a high range for TCR: >2.5°C to 3.6°C However, this estimate may be affected by different mechanisms by which solar forcing affects climate (see Box 10.2). The authors attempt to minimize possible aliasing with the response to other forcings in the 20th century and with internal climate variability, although some influence by them cannot be ruled out.

Rogelj et al. (2012) take a somewhat different approach, using a simple climate model to match the distribution of TCR to observational constraints and a consensus distribution of ECS (which will itself have been informed by recent climate change), following Meinshausen et al. (2009). Harris et al. (2013) estimate a distribution for TCR based on a large sample of emulated GCM equilibrium responses, constrained by multiannual mean observations of recent climate and adjusted to account for additional uncertainty associated with model structural deficiencies (Sexton et al., 2012). The equilibrium responses are scaled by global temperature changes associated with the sampled model variants, reweighting the projections based on the likelihood that they correctly replicate observed historical changes in surface temperature, to predict the TCR distribution. Both of these studies represent a combination of multiple lines of evidence, although still strongly informed by recent observed climate change, and hence are assessed here for completeness.

Based on this evidence, including the new 21st century observations that were not yet available to AR4, we conclude that, on the basis of constraints provided by recent observed climate change, TCR is *likely* to lie in the range 1°C to 2.5°C and *extremely unlikely* to be greater than 3°C. This range for TCR is smaller than given at the time of AR4, due to the stronger observational constraints and the wider range of studies now available. Our greater confidence in excluding high values of TCR arises primarily from higher and more confident estimates of past forcing: estimates of TCR are not strongly dependent on observations of ocean heat uptake.

10.8.2 Constraints on Long-Term Climate Change and the Equilibrium Climate Sensitivity

The equilibrium climate sensitivity (ECS) is defined as the warming in response to a sustained doubling of carbon dioxide in the atmosphere relative to pre-industrial levels (see AR4). The equilibrium to which the ECS refers to is generally assumed to be an equilibrium involving the ocean–atmosphere system, which does not include Earth system feedbacks such as long-term melting of ice sheets and ice caps, dust forcing or vegetation changes (see Chapter 5 and Section 12.5.3). The ECS cannot be directly deduced from transient warming attributable to GHGs, or from TCR, as the role of ocean heat uptake has to be taken into account (see Forest et al., 2000; Frame et al., 2005; Knutti and Hegerl, 2008). Estimating the ECS generally relies on the paradigm of a comparison of observed change with results from a physically based climate model, sometimes a very simple one, given uncertainty in the model, data, RF and due to internal variability.

For example, estimates can be based on the simple box model introduced in Section 10.8.1, ECS = $F_{2\times CO2}\ \Delta T/(\Delta F - \Delta Q)$. Simple energy balance calculations rely on a very limited representation of climate response time scales, and cannot account for nonlinearities in the climate system that may lead to changes in feedbacks for different forcings (see Chapter 9). Alternative approaches are estimates that use climate model ensembles with varying parameters that evaluate the ECS of individual models and then infer the probability density function (PDF) for the ECS from the model–data agreement or by using optimization methods (Tanaka et al., 2009).

As discussed in the AR4, the probabilistic estimates available in the literature for climate system parameters, such as ECS and TCR have all been based, implicitly or explicitly, on adopting a Bayesian approach and therefore, even if it is not explicitly stated, involve using some kind of prior information. The shape of the prior has been derived from expert judgement in some studies, observational or experimental evidence in others or from the distribution of the sample of models available. In all cases the constraint by data, for example, from transient warming, or observations related to feedbacks is fairly weak on the upper tail of ECS (e.g., Frame et al., 2005). Therefore, results are sensitive to the prior assumptions (Tomassini et al., 2007; Knutti and Hegerl, 2008; Sanso and Forest, 2009; Aldrin et al., 2012). When the prior distribution fails to taper off for high sensitivities, as is the case for uniform priors (Frame et al., 2005), this leads to long tails (Frame et al., 2005; Annan and Hargreaves, 2011; Lewis, 2013). Uniform priors have been criticized (e.g., Annan and Hargreaves, 2011; Pueyo, 2012; Lewis, 2013) since results assuming a uniform prior in ECS translates instead into a strongly structured prior on climate feedback parameter and vice versa (Frame et al., 2005; Pueyo, 2012). Objective Bayesian analyses attempt to avoid this paradox by using a prior distribution that is invariant to parameter transforms and rescaling, for example, a Jeffreys prior (Lewis, 2013). Estimated probability densities based on priors that are strongly non-uniform in the vicinity of the best fit to the data, as is typically the case for the Jeffreys prior in this instance, can peak at values very different from the location of the best fit, and hence need to be interpreted carefully. To what extent results are sensitive to priors can be evaluated by using different priors, and this has been done more consistently in studies than at the time of AR4 (see Figure 10.20b) and is assessed where available, illustrated in Figure 10.20. Results will also be sensitive to the extent to which uncertainties in forcing (Tanaka et al., 2009), models and observations and internal climate variability are taken into account, and can be acutely sensitive to relatively arbitrary choices of observation period, choice of truncation in estimated covariance matrices and so forth (Lewis, 2013), illustrating the importance of sensitivity studies. Analyses that make a more complete effort to estimate all uncertainties affecting the model–data comparison lead to more trustworthy results, but end up with larger uncertainties (Knutti and Hegerl, 2008).

The detection and attribution chapter in AR4 (Hegerl et al., 2007b) concluded that 'Estimates based on observational constraints indicate that it is *very likely* that the equilibrium climate sensitivity is larger than 1.5°C with a most likely value between 2°C and 3°C'. The following sections discuss evidence since AR4 from several lines of evidence, followed by an overall assessment of ECS based on observed climate changes, and a subset of available new estimates is shown in Figure 10.20b.

10.8.2.1 Estimates from Recent Temperature Change

As estimates of ECS based on recent temperature change can only sample atmospheric feedbacks that occur with presently evolving climate change, they provide information on the 'effective climate sensitivity' (e.g., Forest et al., 2008). As discussed in AR4, analyses based on global scale data find that within data uncertainties, a strong aerosol forcing or a large ocean heat uptake might have masked a strong greenhouse warming (see, e.g., Forest et al., 2002; Frame et al., 2005; Stern, 2006; Roe and Baker, 2007; Hannart et al., 2009; Urban and Keller, 2009; Church et al., 2011). This is consistent with the finding that a set of models with a large range of ECS and aerosol forcing could be consistent with the observed warming (Kiehl, 2007). Consequently, such analyses find that constraints on aerosol forcing are essential to provide tighter constraints on future warming (Tanaka et al., 2009; Schwartz et al., 2010). Aldrin et al. (2012) analyse the observed record from 1850 to 2007 for hemispheric means of surface temperature, and upper 700 m ocean heat content since 1955. The authors use a simple climate model and a Markov Chain Monte Carlo Bayesian technique for analysis. The authors find a quite narrow range of ECS, which narrows further if using a uniform prior in 1/ECS rather than ECS (Figure 10.20). If observations are updated to 2010 and forcing estimates including further indirect aerosol effects are used (following Skeie et al., 2011), this yields a reduced upper tail (see Figure 10.20b, dash dotted). However, this estimate involves a rather simple model for internal variability, hence may underestimate uncertainties. Olson et al. (2012) use similar global scale constraints and surface temperature to 2006, and ocean data to 2003 and arrive at a wide range if using a uniform prior in ECS, and a quite well constrained range if using a prior derived from current mean climate and Last Glacial Maximum (LGM) constraints (see Figure 10.20b). Some of the differences between Olson et al. (2012) and Aldrin et al. (2012) may be due to structural differences in the model used (Aldrin et al. use a simple EBM while Olson use the UVIC EMIC), some due to different statistical methods and some due to use of global rather than hemispheric temperatures in the latter work. An approach based on regressing forcing histories used in 20th century simulations on observed surface temperatures (Schwartz, 2012) estimates ranges of ECS that encompass the AR4 ranges if accounting for data uncertainty (Figure 10.20). Otto et al. (2013) updated the Gregory et al. (2002) global energy balance analysis (see equation above), using temperature and ocean heat content data to 2009 and estimates of RF that are approximately consistent with estimates from Chapters 7 and 8, and ocean heat uptake estimates that are consistent with Chapter 3 and find that inclusion of recent deep ocean heat uptake and temperature data considerably narrow estimates of ECS compared to results using data to the less recent past.

Estimates of ECS and TCR that make use of both spatial and temporal information, or separate the GHG attributable warming using fingerprint methods, can yield tighter estimates (e.g., Frame et al., 2005; Forest et al., 2008; Libardoni and Forest, 2011). The resulting GHG attributable warming tends to be reasonably robust to uncertainties in aerosol forcing (Section 10.3.1.1.3). Forest et al. (2008) have updated their earlier study using a newer version of the MIT model and five different surface temperature data sets (Libardoni and Forest, 2011). Correction of statistical errors in estimation procedure pointed out by Lewis (see Lewis, 2013) changes their result only slightly (Libardoni

and Forest, 2013). The overarching 5 to 95% range of effective climate sensitivity widens to 1.2°C to 5.3°C when all five data sets are used, and constraints on effective ocean diffusivity become very weak (Forest et al., 2008). Uncertainties would likely further increase if estimates of forcing uncertainty, for example, due to natural forcings, are also included (Forest et al., 2006). Lewis (2013) reanalysed the data used in Forest et al. (2006) using an objective Bayesian method (see discussion at top of section). The author finds that use of a Jeffreys prior narrows the upper tail considerably, to 3.6°C for the 95th percentile. When revising the method, omitting upper air data, and adding 6 more years of data a much reduced 5 to 95% range of 1.2°C to 2.2°C results (see Figure 10.20), similar to estimates by Ring et al. (2012) using data to 2008. Lewis's upper limit extends to 3.0°C if accounting for forcing and surface temperature uncertainty (Lewis, 2013). Lewis (2013) also reports a range of 1.1°C to 2.9°C using his revised diagnostics and the Forest et al. (2006) statistical method, whereas adding 9 more years to the Libardoni and Forest (2013) corrected diagnostic (after Libardoni and Forest, 2011; Figure 10.20; using an expert prior in both cases), does not change results much (Figure 10.20b). The differences between results reported in Forest et al. (2008); Libardoni and Forest (2011); Lewis (2013); Libardoni and Forest (2013) are still not fully understood, but appear to be due to a combination of sensitivity of results to the choice of analysis period as well as differences in diagnostics and statistical approach.

In summary, analyses that use the most recent decade find a tightening of the range of ECS based on a combination of recent heat uptake and surface temperature data. Results consistently give low probability to ECS values under 1.0°C (Figure 10.20). The mode of the PDFs varies considerably with period considered as expected from the influence of internal variability on the single realization of observed climate change. Estimates including the most recent data tend to have reduced upper tails (Libardoni and Forest, 2011; Aldrin et al., 2012 and update; Ring et al., 2012 and update cf. Figure 10.20; Lewis, 2013; Otto et al., 2013), although further uncertainty in statistical assumptions and structural uncertainties in simple models used, as well as neglected uncertainties, for example, in forcings, increase assessed uncertainty.

10.8.2.2 Estimates Based on Top of the Atmosphere Radiative Balance

With the satellite era, measurements are now long enough to allow direct estimates of variations in the energy budget of the planet, although the measurements are not sufficiently accurate to determine absolute top of the atmosphere (TOA) fluxes or trends (see Section 2.3 and Box 13.1). Using a simple energy balance relationship between net energy flow towards the Earth, net forcing and a climate feedback parameter and the satellite measurements Murphy et al. (2009) made direct estimates of the climate feedback parameter as the regression coefficient of radiative response against GMST. The feedback parameter in turn is inversely proportional to the ECS (see above, also Forster and Gregory, 2006). Such regression based estimates are, however, subject to uncertainties (see Section 7.2.5.7; see also, Gregory and Forster, 2008; Murphy and Forster, 2010). Lindzen and Choi (2009) used data from the radiative budget and simple energy balance models over the tropics to investigate feedbacks in climate models. Their result suggests that climate models overestimate the outgoing shortwave radiation compared to Earth Radiation Budget Experiment (ERBE) data, but this result was found unreliable owing to use of a limited sample of periods and of a domain limited to low latitudes (Murphy and Forster, 2010). Lindzen and Choi (2011) address some of these criticisms (Chung et al., 2010; Trenberth et al., 2010), but the results remains uncertain. For example, the lag-lead relationship between TOA balance and SST (Lindzen and Choi, 2011) is replicated by Atmospheric Model Intercomparison Project (AMIP) simulations where SST cannot respond (Dessler, 2011). Hence, as discussed in Section 7.2.5.7, the influence of internal temperature variations on short time scales seriously affects such estimates of feedbacks. In addition, the energy budget changes that are used to derive feedbacks are also affected by RF, which Lindzen and Choi (2009) do not account for. Murphy and Forster (2010) further question if estimates of the feedback parameter are suitable to estimate the ECS, as multiple time scales are involved in feedbacks that contribute to climate sensitivity (Knutti and Hegerl, 2008; Dessler, 2010). Lin et al. (2010a) use data over the 20th century combined with an estimate of present TOA imbalance based on modelling (Hansen et al., 2005a) to estimate the energy budget of the planet and give a best estimate of ECS of 3.1°C, but do not attempt to estimate a distribution that accounts fully for uncertainties. In conclusion, measurement and methodological uncertainties in estimates of the feedback parameter and the ECS from short-term variations in the satellite period preclude strong constraints on ECS. When accounting for these uncertainties, estimates of ECS based on the TOA radiation budget appear consistent with those from other lines of evidence within large uncertainties (e.g., Forster and Gregory, 2006; Figure 10.20b).

10.8.2.3 Estimates Based on Response to Volcanic Forcing or Internal Variability

Some analyses used in AR4 were based on the well observed forcing and responses to major volcanic eruptions during the 20th century. The constraint is fairly weak because the peak response to short-term volcanic forcing depends nonlinearly on ECS (Wigley et al., 2005; Boer et al., 2007). Recently, Bender et al. (2010) re-evaluated the constraint and found a close relationship in 9 out of 10 AR4 models between the shortwave TOA imbalance, the simulated response to the eruption of Mt Pinatubo and the ECS. Applying the constraint from observations suggests a range of ECS of 1.7°C to 4.1°C. This range for ECS is subject to observational uncertainty and uncertainty due to internal climate variability, and is derived from a limited sample of models. Schwartz (2007) tried to relate the ECS to the strength of natural variability using the fluctuation dissipation theorem but studies suggest that the observations are too short to support a well constrained and reliable estimate and would yield an underestimate of sensitivity (Kirk-Davidoff, 2009); and that assuming single time scales is too simplistic for the climate system (Knutti and Hegerl, 2008) . Thus, credible estimates of ECS from the response to natural and internal variability do not disagree with other estimates, but at present cannot provide more reliable estimates of ECS.

10.8.2.4 Paleoclimatic Evidence

Palaeoclimatic evidence is promising for estimating ECS (Edwards et al., 2007). This section reports on probabilistic estimates of ECS derived from paleoclimatic data by drawing on Chapter 5 information

on forcing and temperature changes. For periods of past climate, which were close to radiative balance or when climate was changing slowly, for example, the LGM, radiative imbalance and with it ocean heat uptake is less important than for the present (Sections 5.3.3.1 and 5.3.3.2). Treating the RF due to ice sheets, dust and CO_2 as forcings rather than feedbacks implies that the corresponding RF contributions are associated with considerable uncertainties (see Section 5.2.2.3). Koehler et al. (2010) used an estimate of LGM cooling along with its uncertainties together with estimates of LGM RF and its uncertainty to derive an overall estimate of climate sensitivity. This method accounts for the effect of changes in feedbacks for this very different climatic state using published estimates of changes in feedback factors (see Section 5.3.3.2; Hargreaves et al., 2007; Otto-Bliesner et al., 2009). The authors find a best estimate of 2.4°C and a 5 to 95% range of ECS from 1.4°C to 5.2°C, with sensitivities beyond 6°C difficult to reconcile with the data. In contrast, Chylek and Lohmann (2008b) estimate the ECS to be 1.3°C to 2.3°C based on data for the transition from the LGM to the Holocene. However, the true uncertainties are likely larger due to uncertainties in relating local proxies to large-scale temperature change observed over a limited time (Ganopolski and von Deimling, 2008; Hargreaves and Annan, 2009). The authors also use an aerosol RF estimate that may be high (see response by Chylek and Lohmann, 2008a; Ganopolski and von Deimling, 2008).

At the time of the AR4, several studies were assessed in which parameters in climate models had been perturbed systematically in order to estimate ECS, and further studies have been published since, some making use of expanded data for LGM climate change (see Section 5.3.3.2, Table 5.3). Sometimes substantial differences between estimates based on similar data reflect not only differences in assumptions on forcing and use of data, but also structural model uncertainties, for example, in how feedbacks change between different climatic states (e.g., Schneider von Deimling et al., 2006; Hargreaves et al., 2007; (see also Otto-Bliesner et al., 2009). Holden et al. (2010) analysed which versions of the EMIC Genie are consistent with LGM tropical SSTs and find a 90% range of 2.0°C to 5.0°C. Recently, new data synthesis products have become available for assessment with climate model simulations of the LGM which together with further data cover much more of the LGM ocean and land areas, although there are still substantial gaps and substantial data uncertainty (Section 5.3.3). An analysis of the recent SST and land temperature reconstructions for the LGM compared to simulations with an EMIC suggests a 90% range of 1.4°C to 2.8°C for ECS, with SST data providing a narrower range and lower values than land data only (see Figure 10.20; Schmittner et al., 2011). However, structural model uncertainty as well as data uncertainty may increase this range substantially (Fyke and Eby, 2012; Schmittner et al., 2012). Hargreaves et al. (2012) derived a relationship between ECS and LGM response for seven model simulations from PMIP2 simulations and found a linear relationship between tropical cooling and ECS (see Section 5.3.3.2) which has been used to derive an estimate of ECS (Figure 10.20); and has been updated using PMIP3 simulations (Section 5.3.3.2). However, uncertainties remain as the relationship is dependent on the ensemble of models used.

Estimates of ECS from other, more distant paleoclimate periods (e.g., Royer et al., 2007; Royer, 2008; Pagani et al., 2009; Lunt et al., 2010) are difficult to directly compare, as climatic conditions were very different from today and as climate sensitivity can be state dependent, as discussed above. Also, the response on very long time scales is determined by the Earth System Sensitivity, which includes very slow feedbacks by ice sheets and vegetation (see Section 12.5.3). Paleosens Members (2012) reanalysed the relationship between RF and temperature response from paleoclimatic studies, considering Earth system feedbacks as forcings in order to derive an estimate of ECS that is limited to atmospheric feecbacks (sometimes referred to as Charney sensitivity and directly comparable to ECS), and find that resulting estimates are reasonably consistent over the past 65 million years (see detailed discussion in Section 5.3.1). They estimate a 95% range of 1.1°C to 7.0°C, largely based on the past 800,000 years. However, uncertainties in paleoclimate estimates of ECS are likely to be larger than from the instrumental record, for example, due to changes in feedbacks between different climatic states. In conclusion, estimates of ECS have continued to emerge from palaeoclimatic periods that indicate that ECS is *very likely* less than 6°C and *very likely* greater than 1.0°C (see Section 5.3.3).

10.8.2.5 Combining Evidence and Overall Assessment

Most studies find a lower 5% limit for ECS between 1°C and 2°C (Figure 10.20). The combined evidence thus indicates that the net feedbacks to RF are significantly positive. At present, there is no credible individual line of evidence that yields very high or very low climate sensitivity as best estimate. Some recent studies suggest a low climate sensitivity (Chylek et al., 2007; Schwartz et al., 2007; Lindzen and Choi, 2009). However, these are based on problematic assumptions, for example, about the climate's response time, the cause of climate fluctuations, or neglect uncertainty in forcing, observations and internal variability (as discussed in Foster et al., 2008; Knutti and Hegerl, 2008; Murphy and Forster, 2010). In some cases the estimates of the ECS have been refuted by testing the method of estimation with a climate model of known sensitivity (e.g., Kirk-Davidoff, 2009).

Several authors (Annan and Hargreaves, 2006; Hegerl et al., 2006; Annan and Hargreaves, 2010) had proposed combining estimates of climate sensitivity from different lines of evidence by the time of AR4; these and recent work is shown in the panel 'combined' in Figure 10.20. Aldrin et al. (2012) combined the Hegerl et al. (2006) estimate based on the last millennium with their estimate based on the 20th century; and Olson et al. (2012) combined weak constraints from climatology and the LGM in their prior, updated by data on temperature changes. This approach is robust only if the lines of evidence used are truly independent. The latter is hard to evaluate when using prior distributions based on expert knowledge (e.g., Libardoni and Forest, 2011). If lines of evidence are not independent, overly confident assessments of equilibrium climate sensitivity may result (Henriksson et al., 2010; Annan and Hargreaves, 2011).

In conclusion, estimates of the Equilibrium Climate Sensitivity (ECS) based on multiple and partly independent lines of evidence from observed climate change, including estimates using longer records of surface temperature change and new palaeoclimatic evidence, indicate that there is *high confidence* that ECS is *extremely unlikely* less than 1°C and *medium confidence* that the ECS is *likely* between 1.5°C and 4.5°C and *very unlikely* greater than 6°C. They complement the

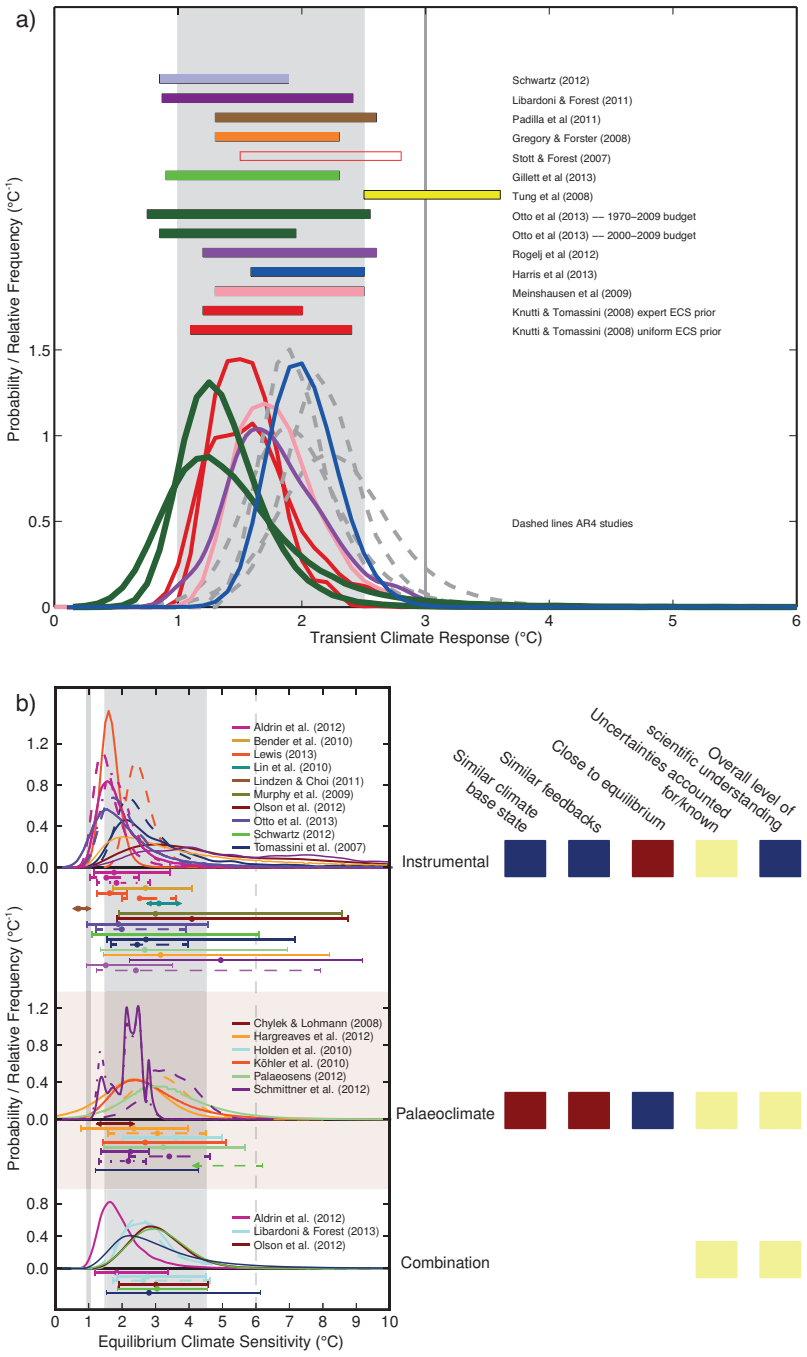

Figure 10.20 | (a) Examples of distributions of the transient climate response (TCR, top) and the equilibrium climate sensitivity (ECS, bottom) estimated from observational constraints. Probability density functions (PDFs), and ranges (5 to 95%) for the TCR estimated by different studies (see text). The grey shaded range marks the *very likely* range of 1°C to 2.5°C for TCR and the grey solid line represents the *extremely unlikely* <3°C upper bound as assessed in this section. Representative distributions from AR4 shown as dashed lines and open bar. (b) Estimates of ECS are compared to overall assessed *likely* range (solid grey), with solid line at 1°C and a dashed line at 6°C. The figure compares some selected old estimates used in AR4 (no labels, thin lines; for references see Supplementary Material) with new estimates available since AR4 (labelled, thicker lines). Distributions are shown where available, together with 5 to 95% ranges and median values (circles). Ranges that are assessed as being incomplete are marked by arrows; note that in contrast to the other estimates Schwartz (2012), shows a sampling range and Chylek and Lohmann a 95% range. Estimates are based on changes over the instrumental period (top row); and changes from palaeoclimatic data (2nd row). Studies that combine multiple lines of evidence are shown in the bottom panel. The boxes on the right-hand side indicate limitations and strengths of each line of evidence, for example, if a period has a similar climatic base state, if feedbacks are similar to those operating under CO_2 doubling, if the observed change is close to equilibrium, if, between all lines of evidence plotted, uncertainty is accounted for relatively completely, and summarizes the level of scientific understanding of this line of evidence overall. A blue box indicates an overall line of evidence that is well understood, has small uncertainty, or many studies and overall *high confidence*. Pale yellow indicates *medium*, and dark red *low*, *confidence* (i.e., poorly understood,very few studies, poor agreement, unknown limitations, after Knutti and Hegerl, 2008). Where available, results are shown using several different prior distributions; for example for Aldrin et al. (2012) solid shows the result using a uniform *prior* in ECS, which is shown as updated to 2010 in dash-dots; dashed: uniform *prior* in 1/ECS; and in bottom panel, result combining with Hegerl et al. (2006) *prior*, For Lewis (2013), dashed shows results using the Forest et al. (2006) diagnostic and an objective Bayesian *prior*, solid a revised diagnostic. For Otto et al. (2013), solid is an estimate using change to 1979–2009, dashed using the change to 2000–2009. Palaeoclimate: Hargreaves et al. (2012) is shown in solid, with dashed showing an update based on PMIP3 simulations (see Chapter 5); For Schmittner et al. (2011), solid is land-and-ocean, dashed land-only, and dash-dotted is ocean-only diagnostic.

evaluation in Chapter 9 and support the overall assessment in Chapter 12 that concludes between all lines of evidence with *high confidence* that ECS is *likely* in the range 1.5°C to 4.5°C. Earth system feedbacks can lead to different, probably larger, warming than indicated by ECS on very long time scales.

10.8.3 Consequences for Aerosol Forcing and Ocean Heat Uptake

Some estimates of ECS also yield estimates of aerosol forcing that are consistent with observational records, which we briefly mention here. Note that the estimate will reflect any forcings with a time or time–space pattern resembling aerosol forcing that is not explicitly included in the overall estimate (see discussion in Olson et al., 2012), for example, BC on snow; and should hence be interpreted as an estimate of aerosol plus neglected forcings. Estimates will also vary with the method applied and diagnostics used (e.g., analyses including spatial information will yield stronger results). Murphy et al. (2009) use correlations between surface temperature and outgoing shortwave and longwave flux over the satellite period to estimate how much of the total recent forcing has been reduced by aerosol total reflection, which they estimate as –1.1 ± 0.4 W m^{-2} from 1970 to 2000 (1 standard deviation), while Libardoni and Forest (2011), see also Forest et al. (2008), based on the 20th century, find somewhat lower estimates, namely a 90% bound of –0.83 to –0.19 W m^{-2} for the 1980s relative to preindustrial. Lewis (2013), using similar diagnostics but an objective Bayesian method, estimates a total aerosol forcing of about –0.6 to –0.1W m^{-2} or –0.6 to 0.0 W m^{-2} dependent on diagnostic used. The range of the aerosol forcing estimates that are based on the observed climate change are in-line with the expert judgement of the effective RF by aerosol radiation and aerosol cloud interactions combined (ERFaci+ari; Chapter 7) of –0.9 W m^{-2} with a range from –1.9 to –0.1 W m^{-2} that has been guided by climate models that include aerosol effects on mixed-phase and convective clouds in addition to liquid clouds, satellite studies and models that allow cloud-scale responses (see Section 7.5.2).

Several estimates of ECS also estimate a parameter that describe the efficiency with which the ocean takes up heat, e.g., effective global vertical ocean diffusivity (e.g., Tomassini et al., 2007; Forest et al., 2008; Olson et al., 2012; Lewis, 2013). Forest and Reynolds (2008) find that the effective global ocean diffusivity K_v in many of the CMIP3 models lies above the median value based on observational constraints, resulting in a positive bias in their ocean heat uptake. Lewis (2013) similarly finds better agreement for small values of effective ocean diffusivity. However, such a finding was very sensitive to data sets used for surface temperature (Libardoni and Forest, 2011) and ocean data (Sokolov et al., 2010), is somewhat sensitive to the diagnostic applied (Lewis, 2013), and limited by difficulties observing heat uptake in the deep ocean (see, e.g., Chapters 3 and 13). Olson et al. (2012) and Tomassini et al. (2007) find that data over the historical period provide only a weak constraint on background ocean effective diffusivity. Comparison of the vertical profiles of temperature and of historical warming in models and observations suggests that the ocean heat uptake efficiency may be typically too large (Kuhlbrodt and Gregory, 2012; Section 13.4.1; see also Sections 9.4.2, 10.4.1, 10.4.3). If effective diffusivity were high in models this might lead to a tendency to bias ocean warming high relative to surface warming; but this uncertainty makes only a small contribution to uncertainty in TCR (Knutti and Tomassini, 2008; Kuhlbrodt and Gregory, 2012; see Section 13.4.1). Nonetheless, ocean thermal expansion and heat content change simulated in CMIP5 models show relatively good agreement with observations, although this might also be due to a compensation between ocean heat uptake efficiency and atmospheric feedbacks (Kuhlbrodt and Gregory, 2012). In summary, constraints on effective ocean diffusivity are presently not conclusive.

10.8.4 Earth System Properties

A number of papers have found the global warming response to CO_2 emissions to be determined primarily by total cumulative emissions of CO_2, irrespective of the timing of those emissions over a broad range of scenarios (Allen et al., 2009; Matthews et al., 2009; Zickfeld et al., 2009; Section 12.5.4.2), although Bowerman et al. (2011) find that, when scenarios with persistent 'emission floors' are included, the strongest predictor of peak warming is cumulative emissions to 2200. Moreover, the ratio of global warming to cumulative carbon emissions, known variously as the Absolute Global Temperature Change Potential (AGTP; defined for an infinitesimal pulse emission) (Shine et al., 2005), the Cumulative Warming Commitment (defined based on peak warming in response to a finite injection; CWC) (Allen et al., 2009) or the Carbon Climate Response (CCR) (Matthews et al., 2009), is approximately scenario-independent and constant in time.

The ratio of CO_2-induced warming realized by a given year to cumulative carbon emissions to that year is known as the Transient Climate Response to cumulative CO_2 Emissions (TCRE, see Chapter 12). TCRE depends on TCR and the Cumulative Airborne Fraction (CAF), which is the ratio of the increased mass of CO_2 in the atmosphere to cumulative CO_2 emissions (not including natural fluxes and those arising from Earth system feedbacks) over a long period, typically since pre-industrial times (Gregory et al., 2009): $\text{TCRE} = \text{TCR} \times \text{CAF}/C_0$, where C_0 is the mass of carbon (in the form of CO_2) in the pre-industrial atmosphere (590 PgC). Given estimates of CAF to the time of CO_2 doubling of 0.4 to 0.7 (Zickfeld et al., 2013), we therefore expect values of TCRE, if expressed in units of °C per 1000 PgC, to be similar to or slightly lower than, and more uncertain than, values of TCR (Gillett et al., 2013).

TCRE may be estimated from observations by dividing an estimate of warming to date attributable to CO_2 by historical cumulative carbon emissions, which gives a 5 to 95% range of 0.7°C to 2.0°C per 1000 PgC (Gillett et al., 2013), 1.0°C to 2.1°C per 1000 PgC (Matthews et al., 2009) or 1.4°C to 2.5°C per 1000 PgC (Allen et al., 2009), the higher range in the latter study reflecting a higher estimate of CO_2-attributable warming to 2000. The peak warming induced by a given total cumulative carbon emission (Peak Response to Cumulative Emissions (PRCE)) is less well constrained, since warming may continue even after a complete cessation of CO_2 emissions, particularly in high-response models or scenarios. Using a combination of observations and models to constrain temperature and carbon cycle parameters in a simple climate-carbon-cycle model, (Allen et al., 2009), obtain a PRCE 5 to 95% confidence interval of 1.3°C to 3.9°C per 1000 PgC. They also report that (Meinshausen et al., 2009) obtain a 5 to 95% range in PRCE of 1.1°C to 2.7°C per 1000 PgC using a Bayesian approach with a different simple model, with climate parameters constrained

by observed warming and carbon cycle parameters constrained by the C4MIP simulations (Friedlingstein et al., 2006).

The ratio of warming to cumulative emissions, the TCRE, is assessed to be *likely* between 0.8°C and 2.5°C per 1000 PgC based on observational constraints. This implies that, for warming due to CO_2 emissions alone to be *likely* less than 2°C at the time CO_2 emissions cease, total cumulative emissions from all anthropogenic sources over the entire industrial era would need to be limited to about 1000 PgC, or one trillion tonnes of carbon (see Section 12.5.4).

10.9 Synthesis

The evidence has grown since the Fourth Assessment Report that widespread changes observed in the climate system since the 1950s are attributable to anthropogenic influences. This evidence is documented in the preceding sections of this chapter, including for near surface temperatures (Section 10.3.1.1), free atmosphere temperatures (Section 10.3.1.2), atmospheric moisture content (Section 10.3.2.1), precipitation over land (Section 10.3.2.2), ocean heat content (Section 10.4.1), ocean salinity (Section 10.4.2), sea level (Section 10.4.3), Arctic sea ice (Section 10.5.1), climate extremes (Section 10.6) and evidence from the last millenium (Section 10.7). These results strengthen the conclusion that human influence on climate has played the dominant role in observed warming since the 1950s. However, the approach taken so far in this chapter has been to examine each aspect of the climate system—the atmosphere, oceans, cryosphere, extremes, and from paleoclimate archives—separately in each section and sub-section. In this section we look across the whole climate system to assess the extent that a consistent picture emerges across sub-systems and climate variables.

10.9.1 Multi-variable Approaches

Multi-variable studies provide one approach to gain a more comprehensive view across the climate system, although there have been relatively few applications of multi-variable detection and attribution studies in the literature. A combined analysis of near-surface temperature from weather stations and free atmosphere temperatures from radiosondes detected an anthropogenic influence on the joint changes in temperatures near the surface and aloft (Jones et al., 2003). In a Bayesian application of detection and attribution Schnur and Hasselmann (2005) combined surface temperature, diurnal temperature range and precipitation into a single analysis and showed strong net evidence for detection of anthropogenic forcings despite low likelihood ratios for diurnal temperature range and precipitation on their own. Barnett et al. (2008) applied a multi-variable approach in analysing changes in the hydrology of the Western United States (see also Section 10.3.2.3).

The potential for a multi-variable analysis to have greater power to discriminate between forced changes and internal variability has been demonstrated by Stott and Jones (2009) and Pierce et al. (2012). In the former case, they showed that a multi-variable fingerprint consisting of the responses of GMST and sub-tropical Atlantic salinity has a higher S/N ratio than the fingerprints of each variable separately. They found reduced detection times as a result of low correlations between the two variables in the control simulation although the detection result depends on the ability of the models to represent the co-variability of the variables concerned. Multi-variable attribution studies potentially provide a stronger test of climate models than single variable attribution studies although there can be sensitivity to weighting of different components of the multi-variable fingerprint. In an analysis of ocean variables, Pierce et al. (2012) found that the joint analysis of temperature and salinity changes yielded a stronger signal of climate change than 'either salinity or temperature alone'.

Further insights can be gained by considering a synthesis of evidence across the climate system. This is the subject of the next subsection.

10.9.2 Whole Climate System

To demonstrate how observed changes across the climate system can be understood in terms of natural and anthropogenic causes Figure 10.21 compares observed and modelled changes in the atmosphere, ocean and cryosphere. The instrumental records associated with each element of the climate system are generally independent (see FAQ 2.1), and consequently joint interpretations across observations from the main components of the climate system increases the confidence to higher levels than from any single study or component of the climate system. The ability of climate models to replicate observed changes (to within internal variability) across a wide suite of climate indicators also builds confidence in the capacity of the models to simulate the Earth's climate.

The coherence of observed changes for the variables shown in Figure 10.21 with climate model simulations that include anthropogenic and natural forcing is remarkable. Surface temperatures over land, SSTs and ocean heat content changes show emerging anthropogenic and natural signals with a clear separation between the observed changes and the alternative hypothesis of just natural variations (Figure 10.21, Global panels). These signals appear not just in the global means, but also at continental and ocean basin scales in these variables. Sea ice emerges strongly from the range expected from natural variability for the Arctic and Antarctica remains broadly within the range of natural variability consistent with expectations from model simulations including anthropogenic forcings.

Table 10.1 illustrates a larger suite of detection and attribution results across the climate system than summarized in Figure 10.21. These results include observations from both the instrumental record and paleo-reconstructions on a range of time scales ranging from daily extreme precipitation events to variability over millennium time scales.

From up in the stratosphere, down through the troposphere to the surface of the Earth and into the depths of the oceans there are detectable signals of change such that the assessed likelihood of a detectable, and often quantifiable, human contribution ranges from *likely* to *extremely likely* for many climate variables (Table 10.1). Indeed to successfully describe the observed warming trends in the atmosphere, ocean and at the surface over the past 50 years, contributions from both anthropogenic and natural forcings are required (e.g., results 1, 2, 3, 4, 5, 7, 9 in Table 10.1). This is consistent with anthropogenic forcings warming the surface of the Earth, troposphere and oceans superimposed with cooling events caused by the three large explosive volcanic eruptions since the 1960's. These two effects (anthropogenic warming and vol-

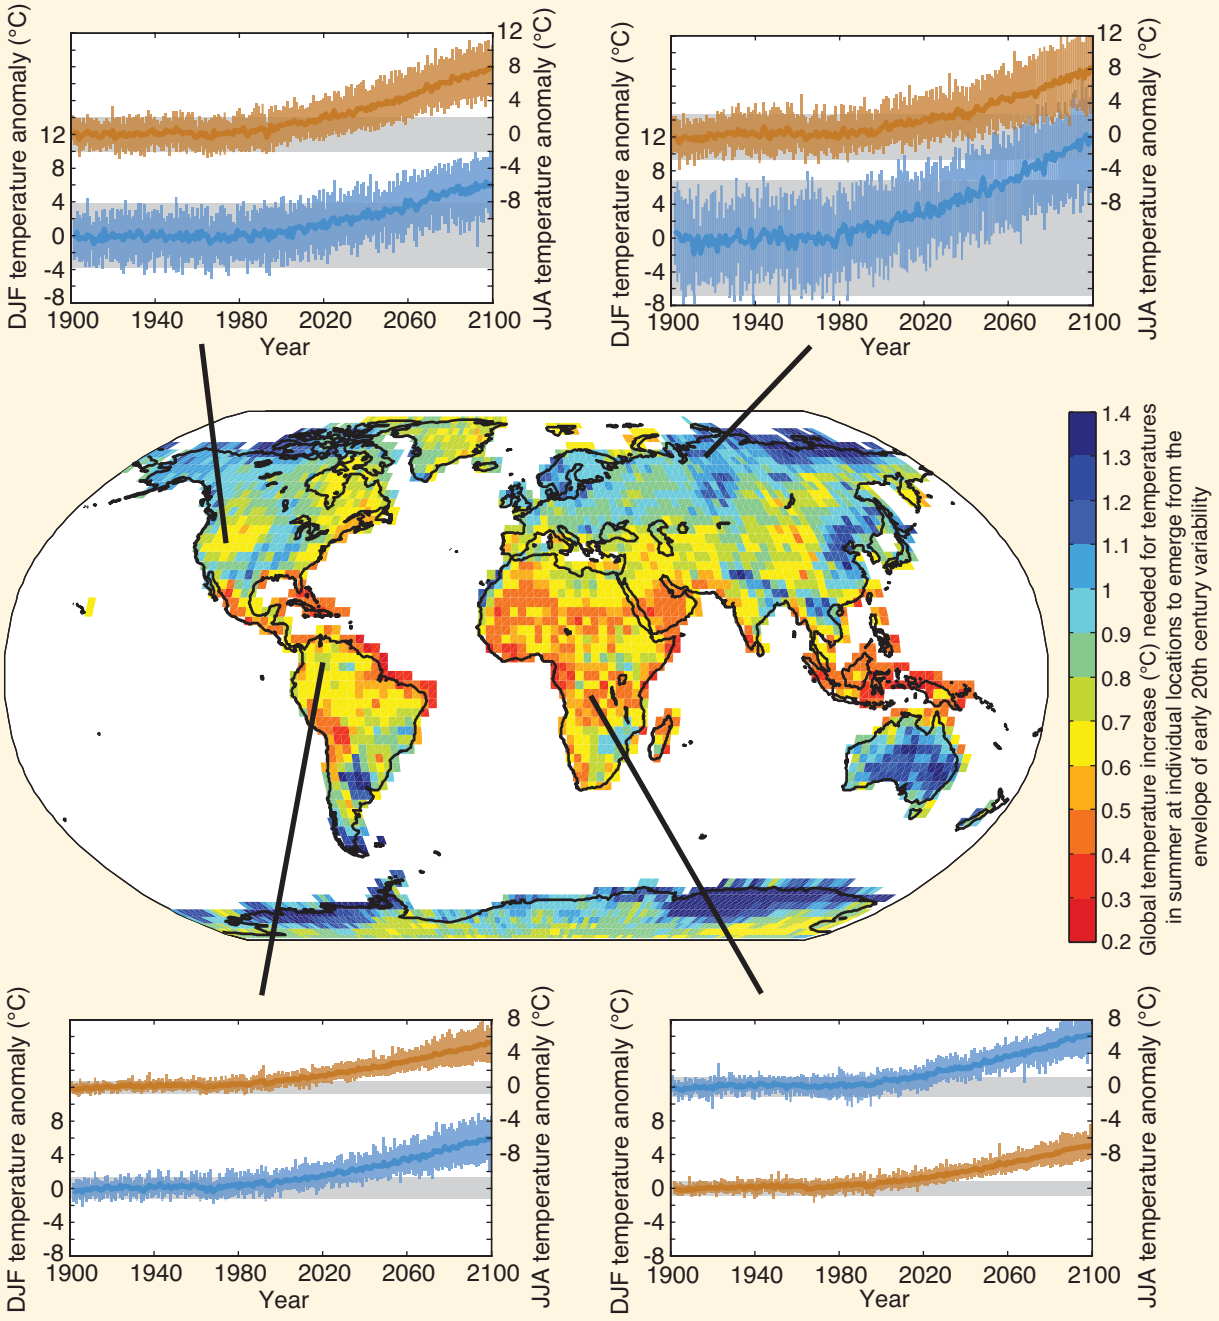
Frequently Asked Questions

FAQ 10.2 | When Will Human Influences on Climate Become Obvious on Local Scales?

Human-caused warming is already becoming locally obvious on land in some tropical regions, especially during the warm part of the year. Warming should become obvious in middle latitudes—during summer at first—within the next several decades. The trend is expected to emerge more slowly there, especially during winter, because natural climate variability increases with distance from the equator and during the cold season. Temperature trends already detected in many regions have been attributed to human influence. Temperature-sensitive climate variables, such as Arctic sea ice, also show detected trends attributable to human influence.

Warming trends associated with global change are generally more evident in averages of global temperature than in time series of local temperature ('local' here refers generally to individual locations, or small regional averages). This is because most of the local variability of local climate is averaged away in the global mean. Multi-decadal warming trends detected in many regions are considered to be outside the range of trends one might expect from natural internal variability of the climate system, but such trends will only become obvious when the local mean climate emerges from the 'noise' of year-to-year variability. How quickly this happens depends on both the rate of the warming trend and the amount of local variability. Future warming trends cannot be predicted precisely, especially at local scales, so estimates of the future time of emergence of a warming trend cannot be made with precision.

In some tropical regions, the warming trend has already emerged from local variability (FAQ 10.2, Figure 1). This happens more quickly in the tropics because there is less temperature variability there than in other parts of the globe. Projected warming may not emerge in middle latitudes until the mid-21st century—even though warming trends there are larger—because local temperature variability is substantially greater there than in the tropics. On a seasonal basis, local temperature variability tends to be smaller in summer than in winter. Warming therefore tends to emerge first in the warm part of the year, even in regions where the warming trend is larger in winter, such as in central Eurasia in FAQ 10.2, Figure 1.



Variables other than land surface temperature, including some oceanic regions, also show rates of long-term change different from natural variability. For example, Arctic sea ice extent is declining very rapidly, and already shows a human influence. On the other hand, local precipitation trends are very hard to detect because at most locations the variability in precipitation is quite large. The probability of record-setting warm summer temperatures has increased throughout much of the Northern Hemisphere . High temperatures presently considered extreme are projected to become closer to the norm over the coming decades. The probabilities of other extreme events, including some cold spells, have lessened.

In the present climate, individual extreme weather events cannot be unambiguously ascribed to climate change, since such events could have happened in an unchanged climate. However the probability of occurrence of such events could have changed significantly at a particular location. Human-induced increases in greenhouse gases are estimated to have contributed substantially to the probability of some heatwaves. Similarly, climate model studies suggest that increased greenhouse gases have contributed to the observed intensification of heavy precipitation events found over parts of the Northern Hemisphere. However, the probability of many other extreme weather events may not have changed substantially. Therefore, it is incorrect to ascribe every new weather record to climate change.

The date of future emergence of projected warming trends also depends on local climate variability, which can temporarily increase or decrease temperatures. Furthermore, the projected local temperature curves shown in FAQ 10.2, Figure 1 are based on multiple climate model simulations forced by the same assumed future emissions scenario. A different rate of atmospheric greenhouse gas accumulation would cause a different warming trend, so the spread of model warming projections (the coloured shading in FAQ 10.2, Figure 1) would be wider if the figure included a spread of greenhouse gas emissions scenarios. The increase required for summer temperature change to emerge from 20th century local variability (regardless of the rate of change) is depicted on the central map in FAQ 10.2, Figure 1.

A full answer to the question of when human influence on local climate will become obvious depends on the strength of evidence one considers sufficient to render something 'obvious'. The most convincing scientific evidence for the effect of climate change on local scales comes from analysing the global picture, and from the wealth of evidence from across the climate system linking many observed changes to human influence. *(continued on next page)*

FAQ 10.2 (continued)

FAQ 10.2, Figure 1 | Time series of projected temperature change shown at four representative locations for summer (red curves, representing June, July and August at sites in the tropics and Northern Hemisphere or December, January and February in the Southern Hemisphere) and winter (blue curves). Each time series is surrounded by an envelope of projected changes (pink for the local warm season, blue for the local cold season) yielded by 24 different model simulations, emerging from a grey envelope of natural local variability simulated by the models using early 20th century conditions. The warming signal emerges first in the tropics during summer. The central map shows the global temperature increase (°C) needed for temperatures in summer at individual locations to emerge from the envelope of early 20th century variability. Note that warm colours denote the smallest needed temperature increase, hence earliest time of emergence. All calculations are based on Coupled Model Intercomparison Project Phase 5 (CMIP5) global climate model simulations forced by the Representative Concentration Pathway 8.5 (RCP8.5) emissions scenario. Envelopes of projected change and natural variability are defined as ±2 standard deviations. (Adapted and updated from Mahlstein et al., 2011.)

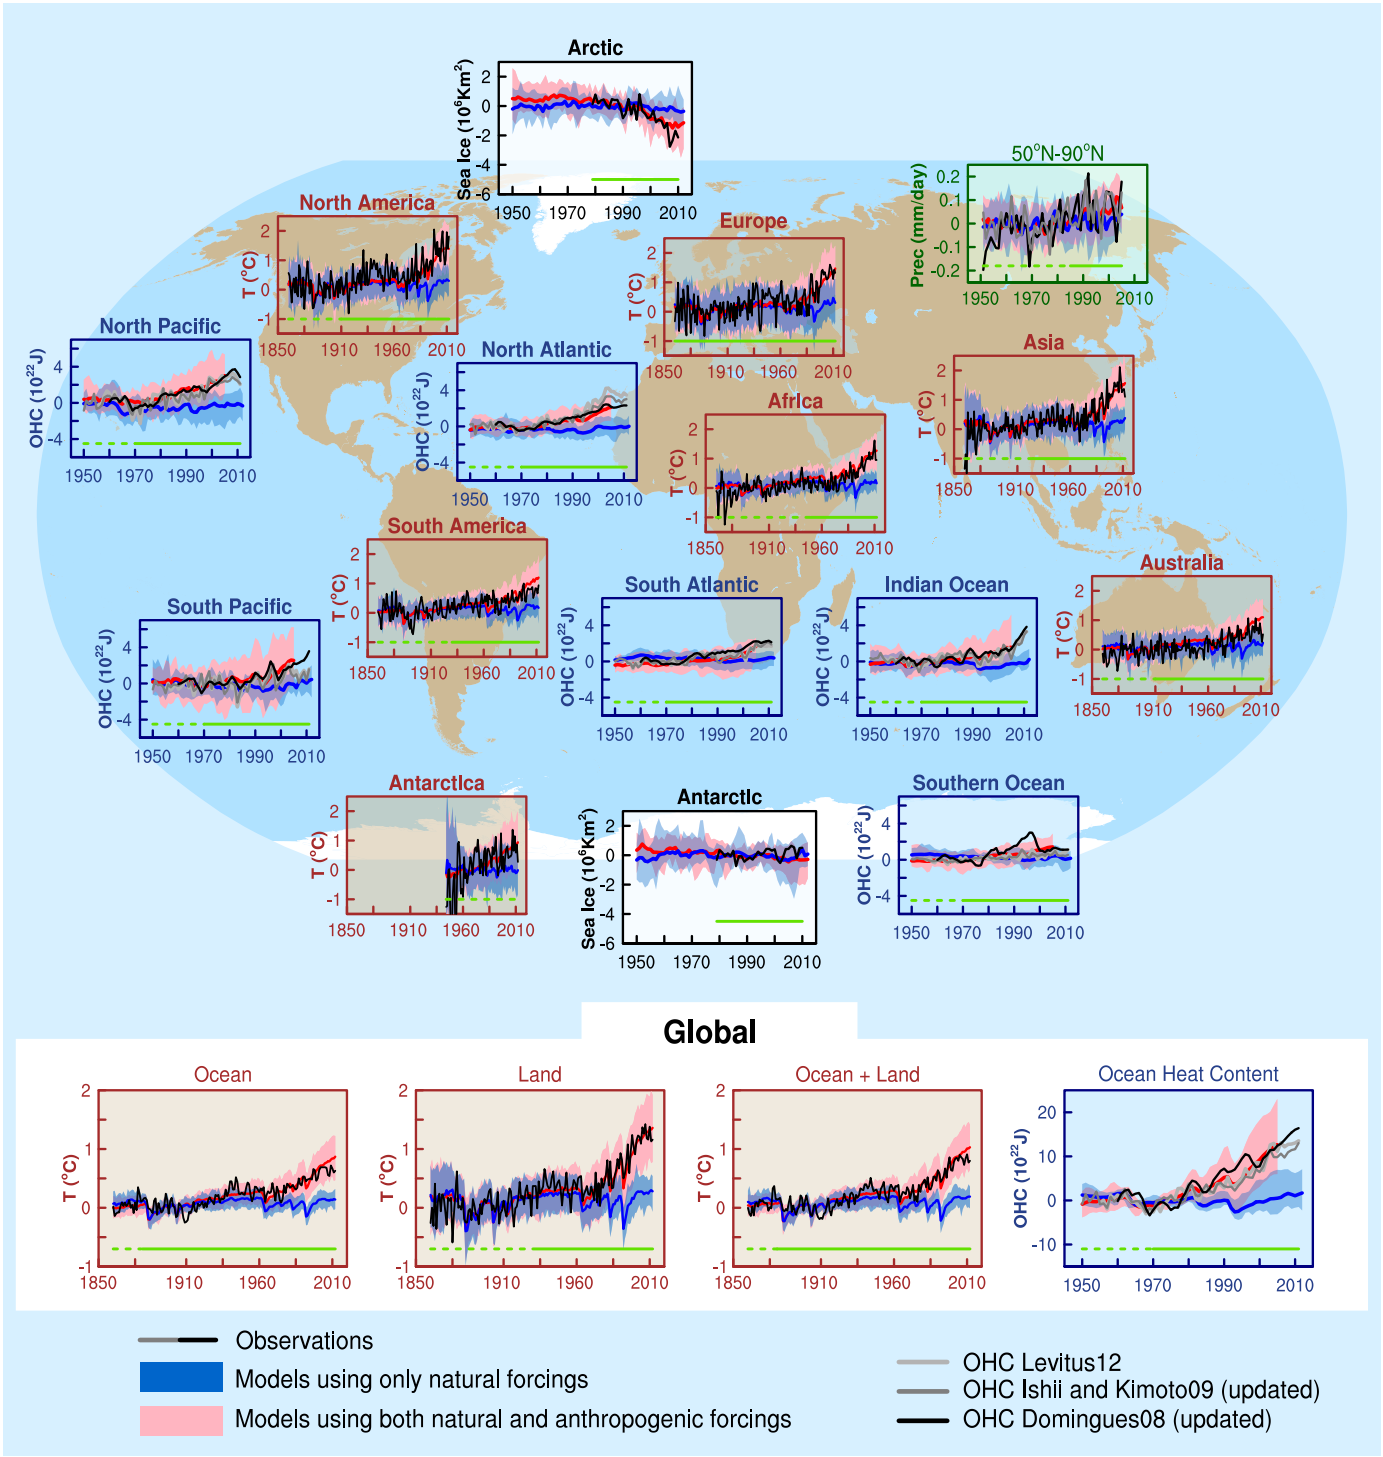


Figure 10.21 | Detection and attribution signals in some elements of the climate system, at regional scales (top panels) and global scales (bottom four panels). Brown panels are land surface temperature time series, green panels are precipitation time series, blue panels are ocean heat content time series and white panels are sea ice time series. Observations are shown on each panel in black or black and shades of grey. Blue shading is the model time series for natural forcing simulations and pink shading is the combined natural and anthropogenic forcings. The dark blue and dark red lines are the ensemble means from the model simulations. All panels show the 5 to 95% intervals of the natural forcing simulations, and the natural and anthropogenic forcing simulations. For surface temperature the results are from Jones et al. (2013) (and Figure 10.1). The observed surface temperature is from Hadley Centre/Climatic Research Unit gridded surface temperature data set 4 (HadCRUT4). Observed precipitation is from Zhang et al. (2007) (black line) and CRU TS 3.0 updated (grey line). Three observed records of ocean heat content (OHC) are shown. Sea ice anomalies (rather than absolute values) are plotted and based on models in Figure 10.16. The green horizontal lines indicate quality of the observations and estimates. For land and ocean surface temperatures panels and precipitation panels, solid green lines at bottom of panels indicate where data spatial coverage being examined is above 50% coverage and dashed green lines where coverage is below 50%. For example, data coverage of Antarctica never goes above 50% of the land area of the continent. For ocean heat content and sea ice panels the solid green line is where the coverage of data is good and higher in quality, and the dashed green line is where the data coverage is only adequate. More details of the sources of model simulations and observations are given in the Supplementary Material (10.SM.1).

canic eruptions) cause much of the observed response (see also Figures 10.5, 10.6, 10.9, 10.14a and 10.21). Both natural and anthropogenic forcings are required to understand fully the variability of the Earth system during the past 50 years.

Water in the free atmosphere is expected to increase, as a consequence of warming of the atmosphere (Section 10.6.1), and atmospheric circulation controls the global distribution of precipitation and evaporation. Simulations show that GHGs increase moisture in the atmosphere and change its transport in such a way as to produce patterns of precipitation and evaporation that are quite distinct from the observed patterns of warming. Our assessment shows that anthropogenic forcings have contributed to observed increases in moisture content in the atmosphere (result 16, *medium confidence*, Table 10.1), to global scale changes in precipitation patterns over land (result 14, *medium confidence*), to a global scale intensification of heavy precipitation in land regions where there observational coverage is sufficient to make an assessment (result 15, *medium confidence*), and to changes in surface and sub-surface ocean salinity (result 11, *very likely*). Combining evidence from both atmosphere and ocean that systematic changes in precipitation over land and ocean salinity can be attributed to human influence supports an assessment that it is *likely* that human influence has affected the global water cycle since 1960.

Warming of the atmosphere and the oceans affects the cryosphere, and in the case of snow and sea ice warming leads to positive feedbacks that amplify the warming response in the atmosphere and oceans. Retreat of mountain glaciers has been observed with an anthropogenic influence detected (result 17, *likely*, Table 10.1), Greenland ice sheet has melted at the edges and accumulating snow at the higher elevations is consistent with GHG warming supporting an assessment for an anthropogenic influence on the negative surface mass balance of Greenland's ice sheet (result 18, *likely*, Table 10.1). Our level of scientific understanding is too low to provide a quantifiable explanation of the observed mass loss of the Antarctic ice sheet (*low confidence*, result 19, Table 10.1). Sea ice in the Arctic is decreasing rapidly and the changes now exceed internal variability and with an anthropogenic contribution detected (result 20, *very likely*, Table 10.1). Antarctic sea ice extent has grown overall over the last 30 years but there is low scientific understanding of the spatial variability and changes in Antarctic sea ice extent (result 21, Table 10.1). There is evidence for an anthropogenic component to observed reductions in NH snow cover since the 1970s (*likely*, result 22, Table 10.1).

Anthropogenic forcing has also affected temperature on continental scales, with human influences having made a substantial contribution to warming in each of the inhabited continents (results 28, *likely*, Table 10.1), and having contributed to the very substantial Arctic warming over the past 50 years (result 29, *likely*, Table 10.1) while because of large observational uncertainties there is *low confidence* in attribution of warming averaged over available stations over Antarctica (result 30, Table 10.1). There is also evidence that anthropogenic forcings have contributed to temperature change in many sub-continental regions (result 32, *likely*, Table 10.1) and that anthropogenic forcings have contributed to the observed changes in the frequency and intensity of daily temperature extremes on the global scale since the mid-20th century (result 8, *very likely*, Table 10.1). Furthermore there is evidence that human influence has substantially increased the probability of occurrence of heat waves in some locations (result 33, *likely*, Table 10.1).

An analysis of these results (from Table 10.1) shows that there is *high confidence* in attributing many aspects of changes in the climate system to human influence including from atmospheric measurements of temperature. Synthesizing the results in Table 10.1 shows that the combined evidence from across the climate system increases the level of confidence in the attribution of observed climate change to human influence and reduces the uncertainties associated with assessments based on a single variable. From this combined evidence, it is *virtually certain* that human influence has warmed the global climate system.

Acknowledgements

We acknowledge the major contributions of the following scientists who took a substantial part in the production of key figures: Beena Balan Sarojini, Oliver Browne, Jara Imbers Quintana, Gareth Jones, Fraser Lott, Irina Mahlstein, Alexander Otto, Debbie Polson, Andrew Schurer, Lijun Tao, and Muyin Wang. We also acknowledge the contributions of Viviane Vasconcellos de Menezes for her work on the production of figures and for her meticulous management of the bibliography database used for this chapter.

Table 10.1 | Synthesis of detection and attribution results across the climate system from this chapter. Note that we follow the guidance note for lead authors of the IPCC AR5 on consistent treatment of uncertainties (Mastrandrea et al., 2011). Where the confidence is *medium* or less there is no assessment given of the quantified likelihood measure, and the table cell is marked not applicable (N/A).

Global Scale Atmospheric Temperature Changes						
1	More than half of the observed increase in global mean surface temperatures from 1951 to 2010 is due to the observed anthropogenic increase in greenhouse gas (GHG) concentrations.	*High*	*Very likely*	Four global surface temperature series (HadCRUT3, HadCRUT4, MLOST, GISTEMP). CMIP3 and CMIP5 models.	· Many formal attribution studies, including optimal fingerprint time-space studies and time series based studies. · Robust evidence. Attribution of more than half of warming since 1950 to GHGs seen in multiple independent analyses using different observational data sets and climate models. · High agreement. Studies agree in robust detection of GHG contribution to observed warming that is larger than any other factor including internal variability.	The observed warming is well understood in terms of contributions of anthropogenic forcings such as greenhouse gases (GHGs) and tropospheric aerosols and natural forcings from volcanic eruptions. Solar forcing is the only other forcing that could explain long-term warming but pattern of warming is not consistent with observed pattern of change in time, vertical change and estimated to be small. AMO could be confounding influence but studies that find significant role for AMO show this does not project strongly onto 60-year trends. (Section 10.3.1.1, Figures 10.4 and 10.5)
2	More than half of the observed increase in global mean surface temperatures from 1951 to 2010 is due to human influence on climate.	*High*	*Extremely likely*	Mutliple CMIP5 models and multiple methodologies.	· Formal attribution studies including different optimal detection methodologies and time series based studies. · Robust evidence of well-constrained estimates of net anthropogenic warming estimated in optimal detection studies. · High agreement. Both optimal detection and time series studies agree in robust detection of anthropogenic influence that is substantially more than half of the observed warming.	The observed warming is well understood in terms of contributions of anthropogenic and natural forcings. Solar forcing and AMO could be confounding influence but are estimated to be smaller than the net effects of human influence. (Section 10.3.1.1, Figures 10.4, 10.5, 10.6)
3	Early 20th century warming is due in part to external forcing.	*High*	*Very likely*	Instrumental global surface temperature series and reconstructions of the last millenium. CMIP3 and CMIP5 models.	· Formal detection and attribution studies looking at early century warming and studies for the last few hundred years. · High agreement across a number of studies in detecting external forcings when including early 20th century period although they vary in contributions from different forcings.	Modelling studies show contribution from external forcings to early century warming. Residual differences between models and observations indicate role for circulation changes as contributor. (Section 10.3.1.1, Figures 10.1, 10.2, 10.6)
4	Warming since 1950 cannot be explained without external forcing.	*High*	*Virtually certain*	Estimates of internal variability from CMIP3 and CMIP5 models, observation based time series and space pattern analyses, and estimating residuals of the non-forced component from paleo data.	· Many, including optimal fingerprint time-space studies, observation based time series and space pattern analyses and paleo data studies. · Robust evidence and high agreement. · Detection of anthropogenic fingerprint robustly seen in independent analyses using different observational data sets, climate models, and methodological approaches.	Based on all evidence above combined. Observed warming since 1950 is very large compared to climate model estimates of internal variability, which are assessed to be adequate at global scale. The Northern Hemisphere (NH) mean warming since 1950 is far outside the range of any similar length trend in residuals from reconstructions of NH mean temperature of the past millennium. The spatial pattern of observed warming differs from those associated with internal variability. (Sections 9.5.3.1, 10.3.1.1, 10.7.1)

Result	(1) Statement about variable or property: time, season	(2) Confidence (*Very high*, *High*, *medium* or *low*, *very low*)	(3) Quantified measure of uncertainty where the probability of the outcome can be quantified (Likelihood given generally only if high or very high confidence)	(4) Data sources Observational evidence (Chapters 2 to 5); Models (Chapter 9)	(5) Type, amount, quality, consistency of evidence from attribution studies and degree of agreement of studies.	(6) Factors contributing to the assessments including physical understanding, observational and modelling uncertainty, and caveats.
5	Anthropogenic forcing has led to a detectable warming of troposphere temperatures since 1961.	*High*	*Likely*	Multiple radiosonde data sets from 1958 and satellite data sets from 1979 to present. CMIP3 and CMIP5 models.	· Formal attribution studies with CMIP3 models (assessed in AR4) and CMIP5 models. · Robust detection and attribution of anthropogenic influence on tropospheric warming with large signal-to-noise (S/N) ratios estimated. · Studies agree in detecting an anthropogenic influence on tropospheric warming trends.	Observational uncertainties in radiosondes are now much better documented than at time of AR4. It is virtually certain that the troposphere has warmed since the mid-20th century but there is only *medium confidence* in the rate and vertical structure of those changes in the NH extratropical troposphere and *low confidence* elsewhere. Most, though not all, CMIP3 and CMIP5 models overestimate the observed warming trend in the tropical troposphere during the satellite period although observational uncertainties are large and outside the tropics and over the period of the radiosonde record beginning in 1961 there is better agreement between simulated and observed trends. (Sections 2.4.4, 9.4.1.4.2, 10.3.1.2, Figure 10.8)
6	Anthropogenic forcing dominated by the depletion of the ozone layer due to ozone depleting substances, has led to a detectable cooling of lower stratosphere temperatures since 1979.	*High*	*Very Likely*	Radiosonde data from 1958 and satellite data from 1979 to present. CCMVal, CMIP3 and CMIP5 simulations.	· A formal optimal detection attribution study using stratosphere resolving chemistry climate models and a detection study analysing the S/N ratio of the data record together with many separate modelling studies and observational studies. · Physical reasoning and model studies show very consistent understanding of observed evolution of stratospheric temperatures, consistent with formal detection and attribution results. · Studies agree in showing very strong cooling in stratosphere that can be explained only by anthropogenic forcings dominated by ozone depleting substances.	New generation of stratosphere resolving models appear to have adequate representation of lower stratospheric variability. Structure of stratospheric temperature trends and variations is reasonably well represented by models. CMIP5 models all include changes in stratospheric ozone while only about half of the models participating in CMIP3 include stratospheric ozone changes. (Sections 9.4.1.4.5, 10.3.1.2.2, Figures10.8 and 10.9)
7	Anthropogenic forcing, particularly GHGs and stratospheric ozone depletion has led to a detectable observed pattern of tropospheric warming and lower stratospheric cooling since 1961.	*High*	*Very likely*	Radiosonde data from 1958 and satellite data from 1979 to present.	· Attribution studies using CMIP3 and CMIP5 models. · Physical reasoning and modelling supports robust expectation of fingerprint of anthropogenic influence of tropospheric warming and lower stratospheric cooling which is robustly detected in multiple observational records. · Fingerprint of anthropogenic influence is detected in different measures of free atmosphere temperature changes including tropospheric warming, and a very clear identification of stratospheric cooling in models that include anthropogenic forcings.	Fingerprint of changes expected from physical understanding and as simulated by models is detected in observations. Understanding of stratospheric changes has improved since AR4. Understanding of observational uncertainty has improved although uncertainties remain particularly in the tropical upper troposphere. (Sections 2.4.4, 10.3.1.2.3, Figures 10.8, 10.9)

Table 10.1 (continued)

Result	(1) Statement about variable or property: time, season	(2) Confidence (*Very high*, *High*, *medium* or *low*, *very low*)	(3) Quantified measure of uncertainty where the probability of the outcome can be quantified (Likelihood given generally only if high or very high confidence)	(4) Data sources Observational evidence (Chapters 2 to 5); Models (Chapter 9)	(5) Type, amount, quality, consistency of evidence from attribution studies and degree of agreement of studies.	(6) Factors contributing to the assessments including physical understanding, observational and modelling uncertainty, and caveats.
8	Anthropogenic forcing has contributed to the observed changes in the frequency and intensity of daily temperatures extremes on the global scale since the mid-20th century.	*High*	*Very Likely*	Indices for frequency and intensity of extreme temperatures including annual maximum and annual minimum daily temperatures, over land areas of the World except parts of Africa, South America and Antarctica. CMIP3 and CMIP5 simulations, 1950–2005.	· Several studies including fingerprint time–space studies. · Detection of anthropogenic influence robustly seen in independent analysis using different statistical methods and different indices.	Expected from physical principles that changes in mean temperature should bring changes in extremes, confirmed by detection and attribution studies. New evidence since AR4 for detection of human influence on extremely warm daytime maximum temperatures and new evidence that influence of anthropogenic forcing can be separately detected from natural forcing. More limited observational data and greater observational uncertainties than for mean temperatures. (Section 10.6.1.1, Figure 10.17)
Oceans						
9	Anthropogenic forcings have made a substantial contribution to upper ocean warming (above 700 m) observed since the 1970s. This anthropogenic ocean warming has contributed to global sea level rise over this period through thermal expansion.	*High*	*Very likely*	Several observational data sets since the 1970s. CMIP3 and CMIP5 models.	· Several new attribution studies detect role of anthropogenic forcing on observed increase in ocean's global heat content with volcanic forcing also contributing to observed variability. · The evidence is very robust, and tested against known structural deficiencies in the observations, and in the models. · High levels of agreement across attribution studies and observation and model comparison studies. The strong physical relationship between thermosteric sea level and ocean heat content means that the anthropogenic ocean warming has contributed to global sea level rise over this period through thermal expansion.	New understanding of the structural errors in the temperature data sets has led to their correction which means that the unexplained multi-decadal scale variability reported in AR4 has largely been resolved as being spurious. The observations and climate simulations have similar trends (including anthropogenic and volcanic forcings) and similar decadal variability. The detection is well above S/N levels required at 1 and 5% significance levels. The new results show the conclusions to be very robust to structural uncertainties in observational data sets and transient climate simulations. (Sections 3.2.5, 10.4.1, 10.4.3, 13.3.6, Figure 10.14)
10	Anthropogenic forcing has contributed to sea level rise through melting glaciers and Greenland ice sheet.	*High*	Likely	Observational evidence of melting glaciers (Section 4.3) and ice sheets (Section 4.4). Global mean sea level budget closure to within uncertainties. (Section13.3.6)	· Several new mass balance studies quantifying glacier and ice sheet melt rates (Section 10.5.2) and their contributions to sea level rise. (Section 13.3)	Strong observational evidence of contribution from melting glaciers and *high confidence* in attribution of glacier melt to human influence. Increasing rates of ice sheet contributions albeit from short observational record (especially of Antarctic mass loss). Current climate models do not represent glacier and ice sheet processes. Natural variability of glaciers and ice sheets not fully understood. (Sections 10.4.3, 10.5.2)

Table 10.1 (continued)

Result	(1) Statement about variable or property: time, season	(2) Confidence (*Very high*, *High*, *medium* or *low*, *very low*)	(3) Quantified measure of uncertainty where the probability of the outcome can be quantified (Likelihood given generally only if high or very high confidence)	(4) Data sources Observational evidence (Chapters 2 to 5); Models (Chapter 9)	(5) Type, amount, quality, consistency of evidence from attribution studies and degree of agreement of studies.	(6) Factors contributing to the assessments including physical understanding, observational and modelling uncertainty, and caveats.
11	The observed ocean surface and sub-surface salinity changes since the 1960s are due, in part, to anthropogenic forcing.	*High*	*Very likely*	Oceans chapter (Section 3.3) and attribution studies in Section 10.4.2.	· Robust observational evidence for amplification of climatological patterns of surface salinity. · CMIP3 simulations show patterns of salinity change consistent with observations, but there are only a few formal attributions studies that include a full characterization of internal variability. · Physical understanding of expected patterns of change in salinity due to changes in water cycle support results from detection and attriution studies.	More than 40 studies of regional, global surface and subsurface salinity observations show patterns of change consistent with acceleration of hydrological water cycle. Climate models that include anthropgenic forcings show the same consistent pattern of surface salinity change. (Sections 3.3.5, 10.4.2, Figure 10.15)
12	Observed increase in surface ocean acidification since 1980s is a resulted of rising atmospheric CO_2	*Very high*	*Very likely*	Evidence from Section 3.8.2 and Box 3.2, Figure 3.18.	· Based on ocean chemistry, expert judgement, and many analyses of time series and other indirect measurements · Robust evidence from time series measurements. Measurements have a high degree of certainty (see Table 3.2) and instrumental records show increase in ocean acidity. · High agreement of the observed trends.	*Very high confidence*, based on the number of studies, the updates to earlier results in AR4, and the very well established physical understanding of gas exchange between atmosphere and surface ocean, and the sources of excess carbon dioxide in the atmosphere. Alternative processes and hypotheses can be excluded. (Section 3.8.2, Box 3.2, Section 10.4.4)
13	Observed pattern of decrease in oxygen content is, in part, attributable to anthropogenic forcing." To correctly read: Observed pattern of decrease in oxygen content from the 1960s to the 1990s is, in part, attributable to anthropogenic forcing.	*Medium*	*About as likely as not*	Evidence from Section 3.8.3 and attribution studies in Section 10.4.4.	· Qualitative expert judgement based on comparison of observed and expected changes in response to increasing CO_2. · Medium evidence. One specific global ocean study, many studies of hydrographic sections and repeat station data, high agreement across observational studies. · Medium agreement. One attribution study, and only limited regional and large-scale modelling and observation comparisons.	Physical understanding of ocean circulation and ventilation, and from the global carbon cycle, and from simulations of ocean oxygen concentrations from coupled bio-geochemical models with OAGCMs. Main uncertainty is observed decadal variability which is not well understood in global and regional inventories of dissolved oxygen in the oceans. (Section 10.4.4)
Water Cycle						
14	Global scale precipitation patterns over land have changed due to anthropogenic forcings including increases in NH mid to high latitudes.	*Medium*	N/A	Multiple observational data sets based on rain gauges over land, with coverage dominated by the NH. CMIP3 and CMIP5 models.	· Several land precipitation studies examining annual and seasonal precipitation. · Evidence for consistency between observed and modelled changes in global precipitation patterns over land regions with sufficient observations. · Medium degree of agreement of studies. Expected anthropogenic fingerprints of changes in zonal mean precipitation found in annual and some seasonal data with some sensitivity of attribution results to observational data set used.	Increases of precipitation at high latitudes of the NH are a robust feature of climate model simulations and are expected from process understanding. Global-land average long-term changes small at present time, whereas decadal variability over some land areas is large. Observations are very uncertain and poor coverage of precipitation expected to make fingerprint of changes much more indistinct. (Sections 2.5.1, 10.3.2.2, Figures 10.10 and 10.11)

(continued on next page)

Table 10.1 (continued)

Result	(1) Statement about variable or property: time, season	(2) Confidence (*Very high*, *High*, *medium* or *low*, *very low*)	(3) Quantified measure of uncertainty where the probability of the outcome can be quantified (Likelihood given generally only if high or very high confidence)	(4) Data sources Observational evidence (Chapters 2 to 5); Models (Chapter 9)	(5) Type, amount, quality, consistency of evidence from attribution studies and degree of agreement of studies.	(6) Factors contributing to the assessments including physical understanding, observational and modelling uncertainty, and caveats.
15	In land regions where observational coverage is sufficient for assessment, anthropogenic forcing has contributed to global-scale intensification of heavy precipitation over the second half of the 20th century.	*Medium*	N/A	Wettest 1-day and 5-day precipitation in a year obtained from rain guage observations, CMIP3 simulations.	· Only one detection and attribution study restricted to NH land where observations were available. · Study found stronger detectability for models with natural forcings but not able to differentiate anthropogenic from natural forcings. · Although only one formal detection and attribution study, observations of a general increase in heavy precipitation at the global scale agree with physical expectations.	Evidence for anthropogenic influence on various aspects of the hydrological cycle that implies extreme precipitation would be expected to increase. There are large observational uncertainties and poor global coverage which makes assessment difficult. (Section 10.6.1.2, Figure 10.11)
16	Anthropogenic contribution to atmospheric specific humidity since 1973.	*Medium*	N/A	Observations of atmospheric moisture content over ocean from satellite; observations of surface humidity from weather stations and radiosondes over land.	· Detection and attribution studies of both surface humidity from weather stations over land and atmospheric moisture content over oceans from satellites. · Detection of anthropogenic influence on atmospheric moisture content over oceans robust to choice of models. · Studies looking at different variables agree in detecting specific humidity changes.	Recent reductions in relative humidity over land and levelling off of specific humidity not fully understood. Length and quality of observational data sets limit detection and attribution and assimilated analyses not judged sufficiently reliable for detection and attribution. (Section 10.3.2.1)
Hemispheric Scale Changes; Basin Scale Changes						
Cryosphere						
17	A substantial part of glaciers mass loss since the 1960's is due to human influence.	*High*	*Likely*	Robust agreement from long-term glacier records. (Section 4.3.3)	· Several new recent studies since last assessment. · High agreement across a limited number of studies.	Well established records of glacier length, and better methods of estimating glacier volumes and mass loss. Better characterization of internal variability, and better understanding of the response to natural variability, and local land cover change. (Sections 4.3.3, 10.5.2)
18	Anthropogenic forcing has contributed to surface melting of the Greenland ice sheet since 1993.	*High*	*Likely*	Robust agreement across *in situ* and satellite derived estimates of surface mass balance (Section 4.4). Nested or downscaled model simulations show pattern of change consistent with warming.	· Several new studies since last assessment. · Robust evidence from different sources. · High agreement across a limited number of studies.	Documented evidence of surface mass loss. Uncertainty caused by poor characterization of the internal variability of the surface mass balance (strong dependence on atmospheric variability) that is not well represented in CMIP5 models. (Section 4.4.2, 10.5.2.1)
19	Antarctic ice sheet mass balance loss has a contribution from anthropogenic forcing.	*Low*	N/A	Observational evidence for Antarctic mass sheet loss is well established across a broad range of studies. (Section 4.4)	· No formal studies exist. Processes for mass loss for Antarctica are not well understood. Regional warming and changed wind patterns (increased westerlies, increase in the Southern Annular Mode (SAM)) could contribute to enhanced melt of Antarctica. High agreement in observational studies.	*Low confidence* assessment based on low scientific understanding. (Sections 4.4.2, 13.4, 10.5.2)
20	Anthropogenic forcing has contributed to the Arctic sea ice loss since 1979.	*High*	*Very likely*	Robust agreement across all observations. (Section 4.2)	· Multiple detection and attribution studies, large number of model simulations and data comparisons for instrumental record. · Robust set of studies of simulations of sea ice and observed sea ice extent. · High agreement between studies of sea ice simulations and observed sea ice extent.	*High confidence* based on documented observations of ice extent loss, and also good evidence for a significant reduction in sea ice volume. The physics of Arctic sea ice is well understood and consistent with the observed warming in the region, and from simulations of Arctic sea ice extent with anthropogenic forcing. (Sections 9.4.3, 10.5.1)

(continued on next page)

Table 10.1 (continued)

Result	(1) Statement about variable or property: time, season	(2) Confidence (*Very high*, *High*, *medium* or *low*, *very low*)	(3) Quantified measure of uncertainty where the probability of the outcome can be quantified (Likelihood given generally only if high or very high confidence)	(4) Data sources Observational evidence (Chapters 2 to 5); Models (Chapter 9)	(5) Type, amount, quality, consistency of evidence from attribution studies and degree of agreement of studies.	(6) Factors contributing to the assessments including physical understanding, observational and modelling uncertainty, and caveats.
21	Incomplete scientific explanations of the observed increase in Antarctic sea ice extent precludes attribution at this time.	N/A	N/A	The increase in sea ice extent in observations is robust, based on satellite measurements and ship-based measurements. (Section 4.5.2)	· No formal attribution studies. · Estimates of internal variability from CMIP5 simulations exceed observed sea ice variability. · Modelling studies have a low level of agreement for observed increase, and there are competing scientific explanations.	*Low confidence* based on low scientific understanding of the spatial variability and changes in the Antarctic sea ice. (Sections 4.5.2, 10.5.1, 9.4.3)
22	There is an anthropogenic component to observed reductions in NH snow cover since 1970	*High*	*Likely*	Observations show decrease in NH snow cover.	· Two snow cover attribution studies. · Decrease in snow cover in the observations are consistent among many studies. (Section 4.5.2, 4.5.3) · Reductions in observed snow cover inconsistent with internal variability and can be explained only by climate models that include anthropogenic forcings.	Expert judgement and attribution studies support the human influence on reduction in snow cover extent. (Sections 4.5.2, 4.5.3, 10.5.3)
Atmospheric Circulation and Patterns of Variability						
23	Human influence has altered sea level pressure patterns globally since 1951.	*High*	*Likely*	An observational gridded data set and reanalyses. Multiple climate models.	· A number of studies find detectable anthropogenic influence on sea level pressure patterns. · Detection of anthropogenic influence is found to be robust to currently sampled modelling and observational uncertainty.	Detectable anthropogenic influence on changes in sea level pressure patterns is found in several attribution studies that sample observational and modelling uncertainty. Observational uncertainties not fully sampled as results based largely on variants of one gridded data set although analyses based on reanalyses also support the finding of a detectable anthropogenic influence. (Section 10.3.3.4)
24	The positive trend in the SAM seen in austral summer since 1951 is due in part to stratospheric ozone depletion.	*High*	*Likely*	Measurements since 1957. Clear signal of SAM trend in December, January and February (DJF) is robust to observational uncertainty.	· Many studies comparing consistency of observed and modelled trends, and consistency of observed trend with simulated internal variability. · Observed trends are consistent with CMIP3 and CMIP5 simulations that include stratospheric ozone depletion. · Several studies show that the observed increase in the DJF SAM is inconsistent with simulated internal variability. High agreement of modelling studies that ozone depletion drives an increase in the DJF SAM index. There is *medium confidence* that GHGs have also played a role.	Consistent result of modelling studies is that the main aspect of the anthropogenically forced response on the DJF SAM is the impact of ozone depletion. The observational record is relatively short, observational uncertainties remain, and the DJF SAM trend since 1951 is only marginally inconsistent with internal variability in some data sets. (Section 10.3.3.3, Figure 10.13)
25	Stratospheric ozone depletion has contributed to the observed poleward shift of the Southern Hadley cell during austral summer.	*Medium*	N/A	Multiple observational lines of evidence for widening but large spread in the magnitude. Reanalysis suggest a southward shift of southern Hadley cell border during DJF which is also seen in CMIP3 and CMIP5 models.	· Consistent evidence for effects of stratospheric ozone depletion. · Evidence from modelling studies is robust that stratospheric ozone drives a poleward shift of the southern Hadley Cell border during austral summer. The magnitude of the shift is very uncertain and appears to be underestimated by models. There is *medium confidence* that GHGs have also played a role.	The observed magnitude of the tropical belt widening is uncertain. The contribution of internal climate variability to the observed poleward expansion of the Hadley circulation remains very uncertain. (Section 10.3.3.1, Figure 10.12)

(continued on next page)

Table 10.1 (continued)

Result	(1) Statement about variable or property: time, season	(2) Confidence (*Very high*, *High*, *medium* or *low*, *very low*)	(3) Quantified measure of uncertainty where the probability of the outcome can be quantified (Likelihood given generally only if high or very high confidence)	(4) Data sources Observational evidence (Chapters 2 to 5); Models (Chapter 9)	(5) Type, amount, quality, consistency of evidence from attribution studies and degree of agreement of studies.	(6) Factors contributing to the assessments including physical understanding, observational and modelling uncertainty, and caveats.
26	Attribution of changes in tropical cyclone activity to human influence.	*Low*	N/A	Incomplete and short observational records in most basins.	· Formal attribution studies on SSTs in tropics. However, mechanisms linking anthropogenically induced SST increases to changes in tropical cyclone activity poorly understood. · Attribution assessments depend on multi-step attribution linking anthropogenic influence to large-scale drivers and thence to tropical cyclone activity. · Low agreement between studies, medium evidence.	Insufficient observational evidence of multi-decadal scale variability. Physical understanding lacking. There remains substantial disagreement on the relative importance of internal variability, GHG forcing, and aerosols. (Sections 10.6.1.5, 14.6.1)
Millennium Time Scale						
27	External forcing contributed to NH temperature variability from 1400 to 1850, and from 850 to 1400.	*High* for period from 1400 to 1850; *medium* for period from 850 to 1400.	*Very likely* for period from 1400 to 1850.	See Chapter 5 for reconstructions; simulations from PMIP3 and CMIP5 models, with more robust detection results for 1400 onwards.	· A small number of detection and attribution studies and further evidence from climate modelling studies; comparison of models with reconstructions and results from data assimilation. · Robust agreement from a number of studies using a range of reconstructions and models (EBMs to ESMs) that models are able to reproduce key features of last seven centuries. · Detection results and simulations indicate a contribution by external drivers to the warm conditions in the 11th to 12th century, but cannot explain the warmth around the 10th century in some reconstructions.	Large uncertainty in reconstructions particularly for the first half of the millennium but good agreement between reconstructed and simulated large scale features from 1400. Detection of forced influence robust for a large range of reconstructions. Difficult to separate role of individual forcings. Results prior to 1400 much more uncertain, partly due to larger data and forcing uncertainty. (Sections 10.7.1, 10.7.2, 10.7.3)
Continental to Regional Scale Changes						
28	Anthropogenic forcing has made a substantial contribution to warming to each of the inhabited continents.	*High*	*Likely*	Robust observational evidence except for Africa due to poor sampling. Detection and attribution studies with CMIP3 and CMIP5 models.	· New studies since AR4 detect anthropogenic warming on continental and sub-continental scales. · Robust detection of human influence on continental scales agrees with global attribution of widespread warming over land to human influence. · Studies agree in detecting human influence on continental scales.	Anthropogenic pattern of warming widespread across all inhabited continents. Lower S/N ratios at continental scales than global scales. Separation of response to forcings more difficult at these scales. Models have greater errors in representation of regional details. (Section 10.3.1.1,4, Box 11.2)
29	Anthropogenic contribution to very substantial Arctic warming over the past 50 years.	*High*	*Likely*	Adequate observational coverage since 1950s. Detection and attribution analysis with CMIP3 models.	· Multiple models show amplification of Arctic temperatures from anthropogenic forcing. · Large positive Arctic-wide temperature anomalies in observations over last decade and models are consistent only when they include external forcing.	Large temperature signal relative to mid-latitudes but also larger internal variability and poorer observational coverage than at lower latitudes. Known multiple processes including albedo shifts and added heat storage contribute to faster warming than at lower latitudes. (Sections 10.3.1.1.4. 10.5.1.1)

(continued on next page)

Table 10.1 (continued)

Result	(1) Statement about variable or property: time, season	(2) Confidence (*Very high*, *High*, *medium* or *low*, *very low*)	(3) Quantified measure of uncertainty where the probability of the outcome can be quantified (Likelihood given generally only if high or very high confidence)	(4) Data sources Observational evidence (Chapters 2 to 5); Models (Chapter 9)	(5) Type, amount, quality, consistency of evidence from attribution studies and degree of agreement of studies.	(6) Factors contributing to the assessments including physical understanding, observational and modelling uncertainty, and caveats.
30	Human contribution to observed warming averaged over available stations over Antarctica.	*Low*	N/A	Poor observational coverage of Antarctica with most observations around the coast. Detection and attribution studies with CMIP3 and CMIP5 models.	· One optimal detection study, and some modelling studies. · Clear detection in one optimal detection study.	Possible contribution to changes from SAM increase. Residual when SAM induced changes are removed shows warming consistent with expectation due to anthropogenic forcing. High observational uncertainty and sparse data coverage (individual stations only mostly around the coast). (Sections 10.3.1.1.4, 2.4.1.1)
31	Contribution by forcing to reconstructed European temperature variability over last five centuries.	*Medium*	N/A	European seasonal temperatures from 1500 onwards.	· One detection and attribution study and several modelling studies. · Clear detection of external forcings in one study; robust volcanic signal seen in several studies (see also Chapter 5).	Robust volcanic response detected in Epoch analyses in several studies. Models reproduce low-frequency evolution when include external forcings. Uncertainty in overall level of variability, uncertainty in reconstruction particularly prior to late 17th century. (Sections 10.7.2, 5.5.1)
32	Anthropogenic forcing has contributed to temperature change in many sub-continental regions of the world.	*High*	*Likely*	Good observational coverage for many regions (e.g., Europe) and poor for others (e.g., Africa, Arctic). Detection and attribution studies with CMIP3 and CMIP5 models.	· A number of detection and attribution studies have analysed temperatures on scales from Giorgi regions to climate model grid box scale. · Many studies agree in showing that an anthropogenic signal is apparent in many sub-continental scale regions. In some sub-continental-scale regions circulation changes may have played a bigger role.	Larger role of internal variability at smaller scales relative to signal of climate change. In some regions observational coverage is poor. Local forcings and feedbacks as well as circulation changes are important in many regions and may not be well simulated in all regions. (Section 10.3.1.1.4, Box 11.2)
33	Human influence has substantially increased the probability of occurrence of heat waves in some locations.	*High*	*Likely*	Good observational coverage for some regions and poor for others (thus biasing studies to regions where observational coverage is good). Coupled modeling studies examining the effects of anthropogonic warming and the probability of occurrence of very warm seasonal temperatures and targeted experiments with models forced with prescribed sea surface temperatures.	· Multi-step attribution studies of some events including the Europe 2003, Western Russia 2010, and Texas 2011 heatwaves have shown an anthropogenic contribution to their occurrence probability, backed up by studies looking at the overall implications of increasing mean temperatures for the probability of exceeding seasonal mean temperature thresholds in some regions. · To infer the probability of a heatwave, extrapolation has to be made from the scales on which most attribution studies have been carried out to the spatial and temporal scales of heatwaves. · Studies agree in finding robust evidence for anthropogenic influence on increase in probability of occurrence of extreme seasonal mean temperatures in many regions.	In some instances, circulation changes could be more important than thermodynamic changes. This could be a possible confounding influence since much of the magnitude (as opposed to the probability of occurrence) of many heat waves is attributable to atmospheric flow anomalies. (Sections 10.6.1, 10.6.2)

Executive Summary

This chapter assesses the scientific literature describing expectations for near-term climate (present through mid-century). Unless otherwise stated, 'near-term' change and the projected changes below are for the period 2016–2035 relative to the reference period 1986–2005. Atmospheric composition (apart from CO_2; see Chapter 12) and air quality projections through to 2100 are also assessed.

Decadal Prediction

The nonlinear and chaotic nature of the climate system imposes natural limits on the extent to which skilful predictions of climate statistics may be made. Model-based 'predictability' studies, which probe these limits and investigate the physical mechanisms involved, support the potential for the skilful prediction of annual to decadal average temperature and, to a lesser extent precipitation.

Predictions for averages of temperature, over large regions of the planet and for the global mean, exhibit positive skill when verified against observations for forecast periods up to ten years (*high confidence*[1]). Predictions of precipitation over some land areas also exhibit positive skill. Decadal prediction is a new endeavour in climate science. The level of quality for climate predictions of annual to decadal average quantities is assessed from the past performance of initialized predictions and non-initialized simulations. {11.2.3, Figures 11.3 and 11.4}

In current results, observation-based initialization is the dominant contributor to the skill of predictions of annual mean temperature for the first few years and to the skill of predictions of the global mean surface temperature and the temperature over the North Atlantic, regions of the South Pacific and the tropical Indian Ocean for longer periods (*high confidence*). Beyond the first few years the skill for annual and multi-annual averages of temperature and precipitation is due mainly to the specified radiative forcing (*high confidence*). {Section 11.2.3, Figures 11.3 to 11.5}

Projected Changes in Radiative Forcing of Climate

For greenhouse gas (GHG) forcing, the new Representative Concentration Pathway (RCP) scenarios are similar in magnitude and range to the AR4 Special Report on Emission Scenarios (SRES) scenarios in the near term, but for aerosol and ozone precursor emissions the RCPs are much lower than SRES by factors of 1.2 to 3. For these emissions the spread across RCPs by 2030 is much narrower than between scenarios that considered current legislation and maximum technically feasible emission reductions (factors of 2). In the near term, the SRES Coupled Model Intercomparison Project Phase 3 (CMIP3) results, which did not incorporate current legislation on air pollutants, include up to three times more anthropogenic aerosols than RCP CMIP5 results (*high confidence*), and thus the CMIP5 global mean temperatures may be up to 0.2°C warmer than if forced with SRES aerosol scenarios (*medium confidence*). {10.3.1.1.3, Figure 10.4, 11.3.1.1, 11.3.5.1, 11.3.6.1, Figure 11.25, Tables AII.2.16 to AII.2.22 and AII.6.8}

Including uncertainties for the chemically reactive GHG methane gives a range in concentration that is 30% wider than the spread in RCP concentrations used in CMIP5 models (*likely*[2]). By 2100 this range extends 520 ppb above RCP8.5 and 230 ppb below RCP2.6 (*likely*), reflecting uncertainties in emissions from agricultural, forestry and land use sources, in atmospheric lifetimes, and in chemical feedbacks, but not in natural emissions. {11.3.5}

Emission reductions aimed at decreasing local air pollution could have a near-term impact on climate (*high confidence*). Short-lived air pollutants have opposing effects: cooling from sulphate and nitrate; warming from black carbon (BC) aerosol, carbon monoxide (CO) and methane (CH_4). Anthropogenic CH_4 emission reductions (25%) phased in by 2030 would decrease surface ozone and reduce warming averaged over 2036–2045 by about 0.2°C (*medium confidence*). Combined reductions of BC and co-emitted species (78%) on top of methane reductions (24%) would further reduce warming (*low confidence*), but uncertainties increase. {Section 7.6, Chapter 8, 11.3.6.1, Figure 11.24a, 8.7.2.2.2, Table AII.7.5a}

Projected Changes in Near-term Climate

Projections of near-term climate show modest sensitivity to alternative RCP scenarios on global scales, but aerosols are an important source of uncertainty on both global and regional scales. {11.3.1, 11.3.6.1}

Projected Changes in Near-term Temperature

The projected change in global mean surface air temperature will *likely* be in the range 0.3 to 0.7°C (*medium confidence*). This projection is valid for the four RCP scenarios and assumes there will be no major volcanic eruptions or secular changes in total solar irradiance before 2035. A future volcanic eruption similar to the 1991 eruption of Mt Pinatubo would cause a rapid drop in global mean surface air temperature of several tenths °C in the following year, with recovery over the next few years. Possible future changes in solar irradiance

[1] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

[2] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–10 0%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

could influence the rate at which global mean surface air temperature increases, but there is *high confidence* that this influence will be small in comparison to the influence of increasing concentrations of GHGs in the atmosphere. {11.3.6, Figure 11.25}

It is *more likely than not* that the mean global mean surface air temperature for the period 2016–2035 will be more than 1°C above the mean for 1850–1900, and *very unlikely* that it will be more than 1.5°C above the 1850–1900 mean (*medium confidence*). {11.3.6.3}

In the near term, differences in global mean surface air temperature change across RCP scenarios for a single climate model are typically smaller than differences between climate models under a single RCP scenario. In 2030, the CMIP5 ensemble median values differ by at most 0.2ºC between RCP scenarios, whereas the model spread (17 to 83% range) for each RCP is about 0.4ºC. The inter-scenario spread increases in time: by 2050 it is 0.8ºC, whereas the model spread for each scenario is only 0.6ºC. Regionally, the largest differences in surface air temperature between RCP2.6 and RCP8.5 are found in the Arctic. {11.3.2.1.1, 11.3.6.1, 11.3.6.3, Figure 11.24a,b, Table AII.7.5}

It is *very likely* that anthropogenic warming of surface air temperature will proceed more rapidly over land areas than over oceans, and that anthropogenic warming over the Arctic in winter will be greater than the global mean warming over the same period, consistent with the AR4. Relative to natural internal variability, near-term increases in seasonal mean and annual mean temperatures are expected to be larger in the tropics and subtropics than in mid-latitudes (*high confidence*). {11.3.2, Figures 11.10 and 11.11}

Projected Changes in the Water Cycle and Atmospheric Circulation

Zonal mean precipitation will *very likely* increase in high and some of the mid latitudes, and will *more likely than not* decrease in the subtropics. At more regional scales precipitation changes may be influenced by anthropogenic aerosol emissions and will be strongly influenced by natural internal variability. {11.3.2, Figures 11.12 and 11.13}

Increases in near-surface specific humidity over land are *very likely*. Increases in evaporation over land are *likely* in many regions. There is *low confidence* in projected changes in soil moisture and surface run off. {11.3.2, Figure 11.14}

It is *likely* that the descending branch of the Hadley Circulation and the Southern Hemisphere (SH) mid-latitude westerlies will shift poleward. It is *likely* that in austral summer the projected recovery of stratospheric ozone and increases in GHG concentrations will have counteracting impacts on the width of the Hadley Circulation and the meridional position of the SH storm track. Therefore, it is *likely* that in the near term the poleward expansion of the descending southern branch of the Hadley Circulation and the SH mid-latitude westerlies in austral summer will be less rapid than in recent decades. {11.3.2}

There is *medium confidence* in near-term projections of a northward shift of Northern Hemisphere storm tracks and westerlies. {11.3.2}

Projected Changes in the Ocean and Cryosphere

It is *very likely* that globally averaged surface and vertically averaged ocean temperatures will increase in the near term. It is *likely* that there will be increases in salinity in the tropical and (especially) subtropical Atlantic, and decreases in the western tropical Pacific over the next few decades. The Atlantic Meridional Overturning Circulation is *likely* to decline by 2050 (*medium confidence*). However, the rate and magnitude of weakening is very uncertain and, due to large internal variability, there may be decades when increases occur. {11.3.3}

It is *very likely* that there will be further shrinking and thinning of Arctic sea ice cover, and decreases of northern high-latitude spring time snow cover and near surface permafrost (see glossary) as global mean surface temperature rises. For high GHG emissions such as those corresponding to RCP8.5, a nearly ice-free Arctic Ocean (sea ice extent less than 1×10^6 km^2 for at least 5 consecutive years) in September is *likely* before mid-century (*medium confidence*). This assessment is based on a subset of models that most closely reproduce the climatological mean state and 1979 to 2012 trend of Arctic sea ice cover. There is *low confidence* in projected near-term decreases in the Antarctic sea ice extent and volume. {11.3.4}

Projected Changes in Extremes

In most land regions the frequency of warm days and warm nights will *likely* increase in the next decades, while that of cold days and cold nights will decrease. Models project near-term increases in the duration, intensity and spatial extent of heat waves and warm spells. These changes may proceed at a different rate than the mean warming. For example, several studies project that European high-percentile summer temperatures warm faster than mean temperatures. {11.3.2.5.1, Figures 11.17 and 11.18}

The frequency and intensity of heavy precipitation events over land will *likely* increase on average in the near term. However, this trend will not be apparent in all regions because of natural variability and possible influences of anthropogenic aerosols. {11.3.2.5.2, Figures 11.17 and 11.18}

There is *low confidence* in basin-scale projections of changes in the intensity and frequency of tropical cyclones (TCs) in all basins to the mid-21st century. This *low confidence* reflects the small number of studies exploring near-term TC activity, the differences across published projections of TC activity, and the large role for natural variability and non-GHG forcing of TC activity up to the mid-21st century. There is *low confidence* in near-term projections for increased TC intensity in the North Atlantic, which is in part due to projected reductions in North Atlantic aerosols loading. {11.3.2.5.3}

Projected Changes in Air Quality

The range in projections of air quality (O_3 and $PM_{2.5}$ in near-surface air) is driven primarily by emissions (including CH_4), rather than by physical climate change (*medium confidence*). The response of air quality to climate-driven changes is more uncertain than the response to emission-driven changes (*high confidence*). Globally, warming decreases background surface O_3 (*high confidence*). High CH_4 levels (RCP8.5, SRES A2) can offset this decrease, raising 2100 background surface O_3 on average by about 8 ppb (25% of current levels) relative to scenarios with small CH_4 changes (RCP4.5, RCP6.0) (*high confidence*). On a continental scale, projected air pollution levels are lower under the new RCP scenarios than under the SRES scenarios because the SRES did not incorporate air quality legislation (*high confidence*). {11.3.5, 11.3.5.2; Figures 11.22 and 11.23ab, AII.4.2, AII.7.1–AII.7.4}

Observational and modelling evidence indicates that, all else being equal, locally higher surface temperatures in polluted regions will trigger regional feedbacks in chemistry and local emissions that will increase peak levels of O_3 and $PM_{2.5}$ (*medium confidence*). Local emissions combined with background levels and with meteorological conditions conducive to the formation and accumulation of pollution are known to produce extreme pollution episodes on local and regional scales. There is *low confidence* in projecting changes in meteorological blocking associated with these extreme episodes. For $PM_{2.5}$, climate change may alter natural aerosol sources (wildfires, wind-lofted dust, biogenic precursors) as well as precipitation scavenging, but no confidence level is attached to the overall impact of climate change on $PM_{2.5}$ distributions. {11.3.5, 11.3.5.2, Box 14.2}

11.1 Introduction

This chapter describes current scientific expectations for 'near-term' climate. Here 'near term' refers to the period from the present to mid-century, during which the climate response to different emissions scenarios is generally similar. Greatest emphasis in this chapter is given to the period 2016–2035, though some information on projected changes before and after this period (up to mid-century) is also assessed. An assessment of the scientific literature relating to atmospheric composition (except carbon dioxide (CO_2), which is addressed in Chapter 12) and air quality for the near-term and beyond to 2100 is also provided.

This emphasis on near-term climate arises from (1) a recognition of its importance to decision makers in government and industry; (2) an increase in the international research effort aimed at improving our understanding of near-term climate; and (3) a recognition that near-term projections are generally less sensitive to differences between future emissions scenarios than are long-term projections. Climate prediction on seasonal to multi-annual time scales require accurate estimates of the initial climate state with less dependence on changes in external forcing[3] over the period. On longer time scales climate projections rely on projections of external forcing with little reliance on the initial state of internal variability. Estimates of near-term climate depend partly on the committed change (caused by the inertia of the oceans as they respond to historical external forcing), the time evolution of internally generated climate variability and the future path of external forcing. Near-term climate is sensitive to rapid changes in some short-lived climate forcing agents (Jacobson and Streets, 2009; Wigley et al., 2009; UNEP and WMO, 2011; Shindell et al., 2012b).

The need for near-term climate information has spawned a new field of climate science: decadal climate prediction (Smith et al., 2007; Meehl et al., 2009b, 2013d). The Coupled Model Intercomparison Project Phase 5 (CMIP5) experimental protocol includes a sequence of near-term predictions (1 to 10 years) where observation-based information is used to initialize the models used to produce the forecasts. The goal is to exploit the predictability of internally generated climate variability as well as that of the externally forced component. The result depends on the ability of current models to reproduce the observed variability as well as on the accurate depiction of the initial state (see Box 11.1). Skilful multi-annual to decadal climate predictions (in the technical sense of 'skilful' as outlined in 11.2.3.2 and FAQ 11.1) are being produced although technical challenges remain that need to be overcome in order to improve skill. These challenges are now being addressed by the scientific community.

Climate change experiments with models that do not depend on initial condition but on the history and projection of climate forcings (often referred to as 'uninitialized' or 'non-initialized' projections or simply as 'projections') are another component of CMIP5. Such projections have been the main focus of assessments of future climate in previous IPCC assessments and are considered in Chapters 12 to 14. The main focus of attention in past assessments has been on the properties of projections for the late 21st century and beyond. Projections also provide valuable information on externally forced changes to near-term climate, however, and are an important source of information that complements information from the predictions. Projections are also assessed in this chapter.

The objectives of this chapter are to assess the state of the science concerning both near-term predictions and near-term projections. CMIP5 results are considered for the near term as are other published near-term predictions and projections. The chapter consists of four major assessments:

1. The scientific basis for near-term prediction as reflected in estimates of predictability (see Box 11.1), and the dynamical and physical mechanisms underpinning predictability, and the processes that limit predictability (see Section 11.2).

2. The current state of knowledge in near-term prediction (see Section 11.2). Here the emphasis is placed on the results from the decadal (10-year) multi-model prediction experiments in the CMIP5 database.

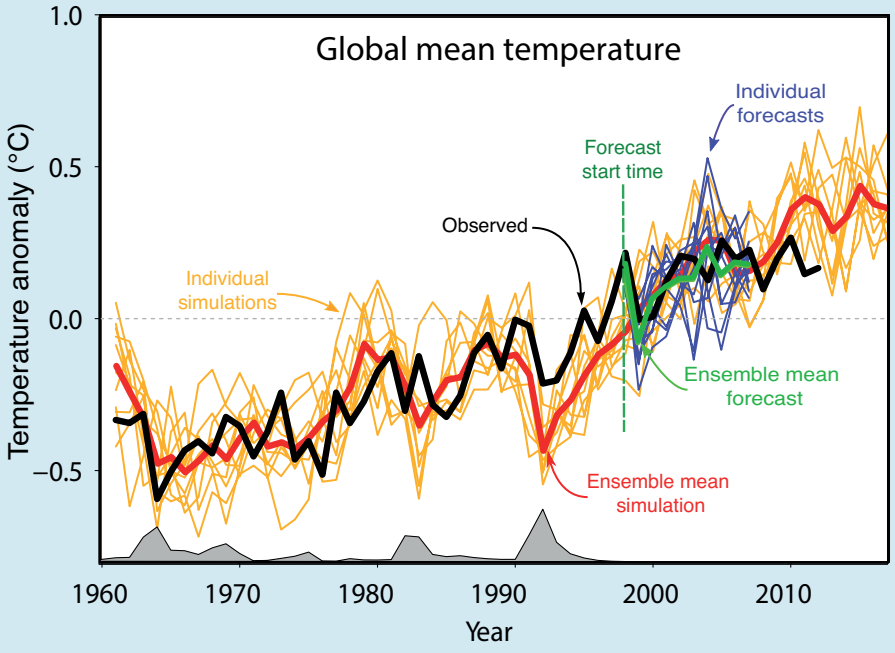
3. The current state of knowledge in near-term projection (see Section 11.3). Here the emphasis is on what the climate in next few decades may look like relative to 1986–2005, based on near-term projections (i.e., the forced climatic response). The focus is on the 'core' near-term period (2016–2035), but some information prior to this period and out to mid-century is also discussed. A key issue is when, where and how the signal of externally forced climate change is expected to emerge from the background of natural climate variability.

4. Projected changes in atmospheric composition and air quality, and their interactions with climate change during the near term and beyond, including new findings from the Atmospheric Chemistry and Climate Model Intercomparison (ACCMIP) initiative.

[3] Seasonal-to-interannual predictions typically include the impact of external forcing.

Box 11.1 | Climate Simulation, Projection, Predictability and Prediction

This section outlines some of the ideas and the terminology used in this chapter.



Internally generated and externally forced climate variability

It is useful for purposes of analysis and description to consider the pre-industrial climate system as being in a state of climatic equilibrium with a fixed atmospheric composition and an unchanging Sun. In this idealized state, naturally occurring processes and interactions within the climate system give rise to 'internally generated' climate variability on many time scales (as discussed in Chapter 1). Variations in climate may also result due to features 'external' to this idealized system. Forcing factors, such as volcanic eruptions, solar variations, anthropogenic changes in the composition of the atmosphere, land use change etc., give rise to 'externally forced' climate variations. In this sense climate system variables such as annual mean temperatures (as in Box 11.1, Figure 1 for instance) may be characterized as a combination of externally forced and internally generated components with $T(t) = T_f(t) + T_i(t)$. This separation of T, and other climate variables, into components is useful when analysing climate behaviour but does not, of course, mean that the climate system is linear or that externally forced and internally generated components do not interact.

Climate simulation

A climate simulation is a model-based representation of the temporal behaviour of the climate system under specified external forcing and boundary conditions. The result is the modelled response to the imposed external forcing combined with internally generated variability. The thin yellow lines in Box 11.1, Figure 1 represent an ensemble of climate simulations begun from pre-industrial conditions with imposed historical external forcing. The imposed external conditions are the same for each ensemble member and differences among the simulations reflect differences in the evolutions of the internally generated component. Simulations are not intended to be forecasts of the observed evolution of the system (the black line in Box 11.1, Figure 1) but to be possible evolutions that are consistent with the external forcings.

In practice, and in Box 11.1, Figure 1, the forced component of the temperature variation is estimated by averaging over the different simulations of $T(t)$ with $T_f(t)$ the component that survives ensemble averaging (the red curve) while $T_i(t)$ averages to near zero for a large enough ensemble. The spread among individual ensemble members (from these or pre-industrial simulations) and their behaviour with time provides some information on the statistics of the internally generated variability. *(continued on next page)*

Box 11.1, Figure 1 | The evolution of observation-based global mean temperature T (the black line) as the difference from the 1986–2005 average together with an ensemble of externally forced simulations to 2005 and projections based on the RCP4.5 scenario thereafter (the yellow lines). The model-based estimate of the externally forced component T_f (the red line) is the average over the ensemble of simulations. To the extent that the red line correctly estimates the forced component, the difference between the black and red lines is the internally generated component T_i for global mean temperature. An ensemble of forecasts of global annual mean temperature, initialized in 1998, is plotted as thin purple lines and their average, the ensemble mean forecast, as the thick green line. The grey areas along the axis indicate the presence of external forcing associated with volcanoes.

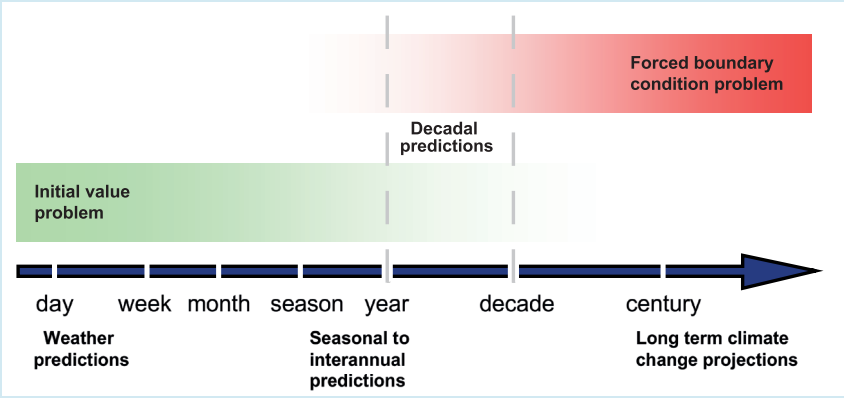
Box 11.1 (continued)

Climate projection

A climate projection is a climate simulation that extends into the future based on a scenario of future external forcing. The simulations in Box 11.1, Figure 1 become climate projections for the period beyond 2005 where the results are based on the RCP4.5 forcing scenario (see Chapters 1 and 8 for a discussion of forcing scenarios).

Climate prediction, climate forecast

A climate prediction or climate forecast is a statement about the future evolution of some aspect of the climate system encompassing both forced and internally generated components. Climate predictions do not attempt to forecast the actual day-to-day progression of the system but instead the evolution of some climate statistic such as seasonal, annual or decadal averages or extremes, which may be for a particular location, or a regional or global average. Climate predictions are often made with models that are the same as, or similar to, those used to produce climate simulations and projections (assessed in Chapter 9). A climate prediction typically proceeds by integrating the governing equations forward in time from observation-based initial conditions. A decadal climate prediction combines aspects of both a forced and an initial condition problem as illustrated in Box 11.1, Figure 2. At short time scales the evolution is largely dominated by the initial state while at longer time scales the influence of the initial conditions decreases and the importance of the forcing increases as illustrated in Box 11.1, Figure 4. Climate predictions may also be made using statistical methods which relate current to future conditions using statistical relationships derived from past system behaviour.



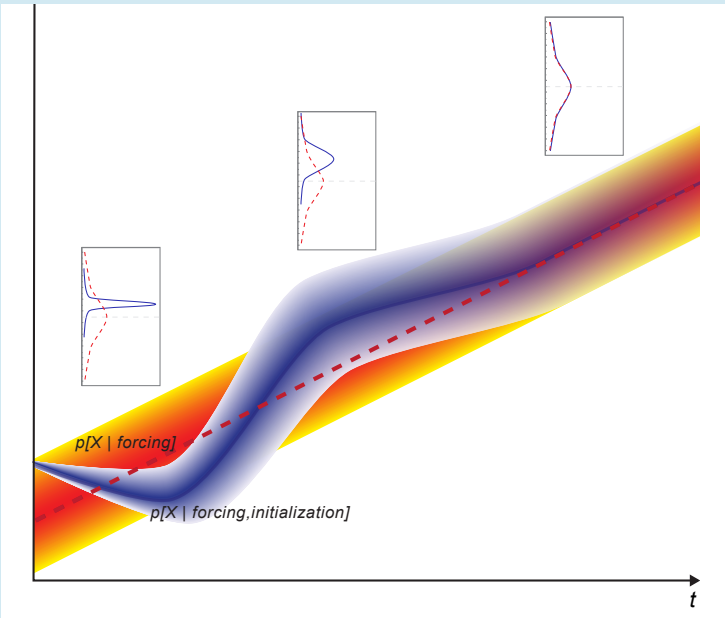
Because of the chaotic and nonlinear nature of the climate system small differences, in initial conditions or in the formulation of the forecast model, result in different evolutions of forecasts with time. This is illustrated in Box 11.1, Figure 1, which displays an ensemble of forecasts of global annual mean temperature (the thin purple lines) initiated in 1998. The individual forecasts are begun from slightly different initial conditions, which are observation-based estimates of the state of the climate system. The thick green line is the average of these forecasts and is an attempt to predict the most probable outcome and to maximize forecast skill. In this schematic example, the 1998 initial conditions for the forecasts are warmer than the average of the simulations. The individual and ensemble mean forecasts exhibit a decline in global temperature before beginning to rise again. In this case, initialization has resulted in more realistic values for the forecasts than for the corresponding simulation, at least for short lead times in the forecast. As the individual forecasts evolve they diverge from one another and begin to resemble the projection results.

A probabilistic view of forecast behaviour is depicted schematically in Box 11.1, Figure 3. The probability distribution associated with the climate simulation of temperature evolves in response to external forcing. By contrast, the probability distribution associated with a climate forecast has a sharply peaked initial distribution representing the comparatively small uncertainty in the observation-based initial state. The forecast probability distribution broadens with time until, ultimately, it becomes indistinguishable from that of an uninitialized climate projection.

Climate predictability

The term 'predictability', as used here, indicates the extent to which even minor imperfections in the knowledge of the current state or of the representation of the system limits knowledge of subsequent states. The rate of separation or divergence of initially close states of the climate system with time (as for the light purple lines in Box 11.1, Figure 1), or the rate of displacement and broadening of its

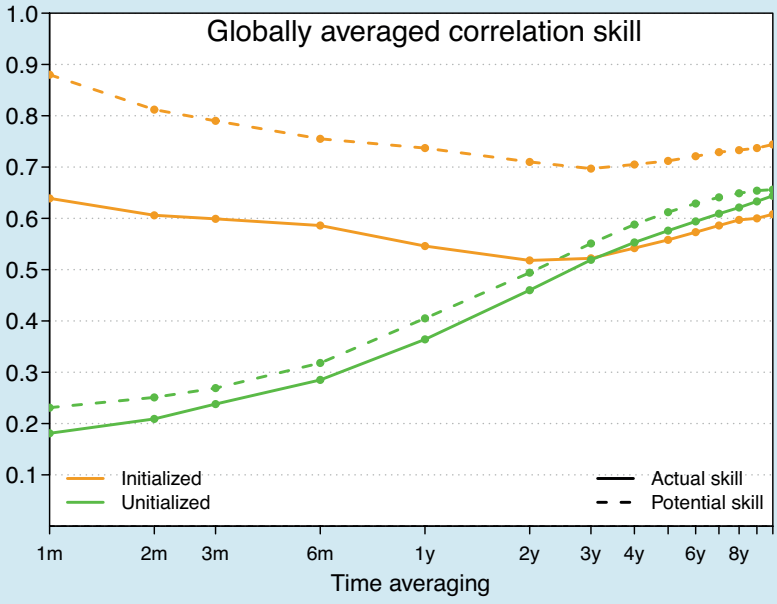
(continued on next page)



Box 11.1, Figure 2 | A schematic illustrating the progression from an initial-value based prediction at short time scales to the forced boundary-value problem of climate projection at long time scales. Decadal prediction occupies the middle ground between the two. (Based on Meehl et al., 2009b.)

Box 11.1 (continued)

probability distribution (as in Box 11.1, Figure 3) are indications of the system's predictability. If initially close states separate rapidly (or the probability distribution broadens quickly towards the climatological distribution), the predictability of the system is low and vice versa. Formally, predictability in climate science is a feature of the physical system itself, rather than of our 'ability to make skilful predictions in practice'. The latter depends on the accuracy of models and initial conditions and on the correctness with which the external forcing can be treated over the forecast period.



Forecast quality, forecast skill

Forecast (or prediction) quality measures the success of a prediction against observation-based information. Forecasts made for past cases, termed retrospective forecasts or hindcasts, may be analysed to give an indication of the quality that may be expected for future forecasts for a particular variable at a particular location.

Box 11.1, Figure 3 | A schematic representation of prediction in terms of probability. The probability distribution corresponding to a forced simulation is in red, with the deeper shades indicating higher probability. The probabilistic forecast is in blue. The sharply peaked forecast distribution based on initial conditions broadens with time as the influence of the initial conditions fades until the probability distribution of the initialized prediction approaches that of an uninitialized projection. (Based on Branstator and Teng, 2010.)

The relative importance of initial conditions and of external forcing for climate prediction, as depicted schematically in Box 11.1, Figure 2, is further illustrated in the example of Box 11.1, Figure 4 which plots correlation measures of both forecast skill and predictability for temperature averages over the globe ranging from a month to a decade. Initialized forecasts exhibit enhanced values compared to uninitialized simulations for shorter time averages but the advantage declines as averaging time increases and the forced component grows in importance.

Box 11.1, Figure 4 | An example of the relative importance of initial conditions and external forcing for climate prediction and predictability. The global average of the correlation skill score of ensemble mean initialized forecasts are plotted as solid orange lines and the corresponding model-based predictability measure as dashed orange lines. The green lines are the same quantities but for uninitialized climate simulations. Results are for temperature averaged over periods from a month to a decade. Values plotted for the monthly average correspond to the first month, those for the annual average to the first year and so on up to the decadal average. (Based on Boer et al., 2013.)

11.2 Near-term Predictions

11.2.1 Introduction

11.2.1.1 Predictability Studies

The innate behaviour of the climate system imposes limits on the ability to predict its evolution. Small differences in initial conditions, external forcing and/or in the representation of the behaviour of the system produce differences in results that limit useful prediction. Predictability studies estimate predictability limits for different variables and regions.

11.2.1.2 Prognostic Predictability Studies

Prognostic predictability studies analyse the behaviour of models integrated forward in time from perturbed initial conditions. The study of Griffies and Bryan (1997) is one of the earliest studies of the predictability of internally generated decadal variability in a coupled atmosphere–ocean climate model. The study concentrates on the North Atlantic and the subsurface ocean temperature while the subsequent studies of Boer (2000) and Collins (2002) deal mainly with surface temperature. Long time scale temperature variability in the North Atlantic has received considerable attention together with its possible connection to the variability of the Atlantic Meridional Overturning Circulation (AMOC) in predictability studies by Collins and Sinha (2003), Collins et al. (2006), Dunstone and Smith (2010), Dunstone et al. (2011), Grotzner et al. (1999), Hawkins and Sutton (2009), Latif et al. (2006, 2007),)Msadek et al. (2010), Persechino et al. (2012), Pohlmann et al. (2004, 2013), Swingedouw et al. (2013), and Teng et al. (2011). The predictability of the AMOC varies among models and, to some extent, with initial model states, ranging from several to 10 or more years. The predictability values are model-based and the realism of the simulated AMOC in the models cannot be easily judged in the absence of a sufficiently long record of observation-based AMOC values. Many predictability studies are based on perturbations to surface quantities but Sevellec and A. Fedorov (2012) and Zanna (2012) note that small perturbations to deep ocean quantities may also affect upper ocean values. The predictability of the North Atlantic sea surface temperature (SST) is typically weaker than that of the AMOC and the connection between the predictability of the AMOC, and the SST is inconsistent among models.

Prognostic predictability studies of the Pacific are less plentiful although Pacific Decadal Variability (PDV) mechanisms (including the Pacific Decadal Oscillation (PDO) and the Inter-decadal Pacific Oscillation (IPO) have received considerable study (see Chapters 2 and 12). Power and Colman (2006) find predictability on multi-year time scales in SST and on decadal time-scales in the sub-surface ocean temperature in the off-equatorial South Pacific in their model. Power et al. (2006) find no evidence for the predictability of inter-decadal changes in the nature of El Niño-Southern Oscillation (ENSO) impacts on Australian rainfall. Sun and Wang (2006) suggest that some of the temperature variability linked to PDV can be predicted approximately 7 years in advance. Teng et al. (2011) investigate the predictability of the first two Empirical Orthogonal Functions (EOFs) of annual mean SST and upper ocean temperature identified with PDV and find predictability of the order of 6 to 10 years. Meehl et al. (2010) consider the predictability of 19-year filtered Pacific SSTs in terms of low order EOFs and find predictability on these long time scales.

Hermanson and Sutton (2010) report that predictable signals in different regions and for different variables may arise from differing initial conditions and that ocean heat content is more predictable than atmospheric and surface variables. Branstator and Teng (2010) analyse upper ocean temperatures, and some SSTs, for averages over the North Atlantic, North Pacific and the tropical Atlantic and Pacific in the National Center for Atmospheric Research (NCAR) model. Predictability associated with the initial state of the system decreases whereas that due to external forcing increases with time. The 'cross-over' time, when the two contributions are equal, is longer in extratropical (7 to 11 years) compared to tropical (2 years) regions and in the North Atlantic compared to the North Pacific. Boer et al. (2013) estimate surface air (rather than upper ocean) temperature predictability in the Canadian Centre for Climate Modelling and Analysis (CCCma) model and find a cross-over time (using a different measure) on the order of 3 years when averaged over the globe.

11.2.1.3 Diagnostic Predictability Studies

Diagnostic predictability studies are based on analyses of the observed record or the output of climate models. Because long data records are needed, diagnostic multi-annual to decadal predictability studies based on observational data are comparatively few. Newman (2007) and Alexander et al. (2008) develop multivariate empirical Linear Inverse Models (LIMs) from observation-based SSTs and find predictability for ENSO and PDV type patterns that are generally limited to the order of a year although exceeding this in some areas. Zanna (2012) develops a LIM based on Atlantic SSTs and infers the possibility of decadal scale predictability. Hoerling et al. (2011) appeal to forced climate change relative to the 1971–2000 period together with the statistics of natural variability to infer the potential for the prediction of temperature over North America for 2011–2020.

Tziperman et al. (2008) apply LIM-based methods to Geophysical Fluid Dynamics Laboratory (GFDL) model output, as do Hawkins and Sutton (2009) and Hawkins et al. (2011) to Hadley Centre model output and find predictability up to a decade or more for the AMOC and North Atlantic SST. Branstator et al. (2012) use analog and multivariate linear regression methods to quantify the predictability of the internally generated component of upper ocean temperature in results from six coupled models. Results differ considerably across models but offer some areas of commonality. Basin-average estimates indicate predictability for up to a decade in the North Atlantic and somewhat less in the North Pacific. Branstator and Teng (2012) assess the predictability of both the internally generated and forced component of upper ocean temperature in results from 12 coupled models participating in CMIP5. They infer potential predictability from initializing the internally generated component for 5 years in the North Pacific and 9 years in the North Atlantic while the forced component dominates after 6.5 and 8 years in the two basins. Results vary among models, although with some agreement for internal component predictability in subpolar gyre regions.

Studies of 'potential predictability' take a number of forms but broadly assume that overall variability may be separated into a long time

scale component of interest and shorter time scale components that are unpredictable on these long time scales, written symbolically as $\sigma^2_X = \sigma^2_v + \sigma^2_\varepsilon$. The fraction $p = \sigma^2_v / \sigma^2_X$ is a measure of potentially predictable variance provided that hypothesis that σ^2_v is zero may be rejected. Small p indicates either a lack of long time scale variability or its smallness as a fraction of the total. Predictability is 'potential' in the sense that the existence of appreciable long time scale variability is not a direct indication that it may be skilfully predicted. There are a number of approaches to estimating potential predictability each with its statistical difficulties (e.g., DelSole and Feng, 2013). At multi-annual time scales the potential predictability of the internally generated component of temperature is studied in Boer (2000), Collins (2002), Pohlmann et al. (2004), Power and Colman (2006) and, in a multi-model context, in Boer (2004) and Boer and Lambert (2008). Power and Colman (2006) report that potential predictability in the ocean tends to increase with latitude and depth. Multi-model results

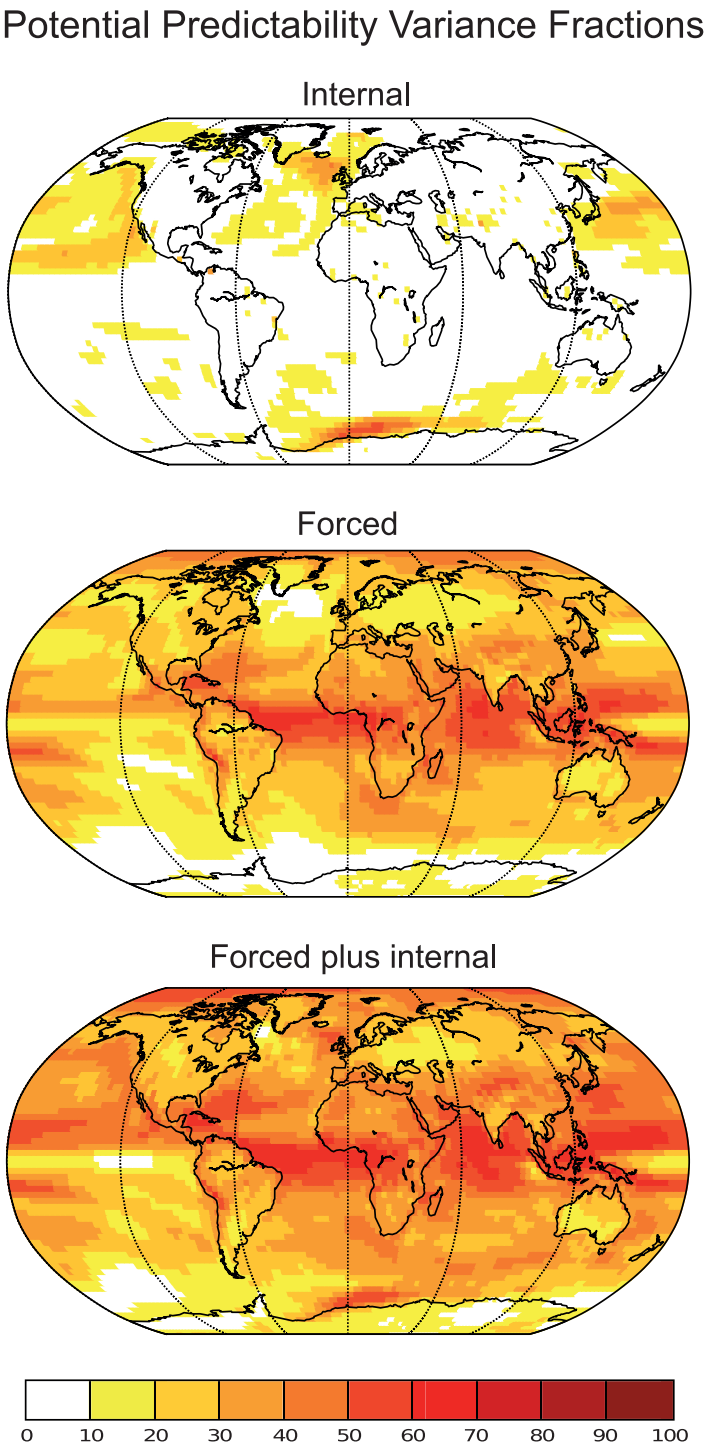


Figure 11.1 | The potential predictability of 5-year means of temperature (lower), the contribution from the forced component (middle) and from the internally generated component (upper). These are multi-model results from CMIP5 RCP4.5 scenario simulations from 17 coupled climate models following the methodology of Boer (2011). The results apply to the early 21st century.

Frequently Asked Questions

FAQ 11.1 | If You Cannot Predict the Weather Next Month, How Can You Predict Climate for the Coming Decade?

Although weather and climate are intertwined, they are in fact different things. Weather is defined as the state of the atmosphere at a given time and place, and can change from hour to hour and day to day. Climate, on the other hand, generally refers to the statistics of weather conditions over a decade or more.

An ability to predict future climate without the need to accurately predict weather is more commonplace that it might first seem. For example, at the end of spring, it can be accurately predicted that the average air temperature over the coming summer in Melbourne (for example) will very likely be higher than the average temperature during the most recent spring—even though the day-to-day weather during the coming summer cannot be predicted with accuracy beyond a week or so. This simple example illustrates that factors exist—in this case the seasonal cycle in solar radiation reaching the Southern Hemisphere—that can underpin skill in predicting changes in climate over a coming period that does not depend on accuracy in predicting weather over the same period.

The statistics of weather conditions used to define climate include long-term averages of air temperature and rainfall, as well as statistics of their variability, such as the standard deviation of year-to-year rainfall variability from the long-term average, or the frequency of days below 5°C. Averages of climate variables over long periods of time are called climatological averages. They can apply to individual months, seasons or the year as a whole. A climate prediction will address questions like: 'How likely will it be that the average temperature during the coming summer will be higher than the long-term average of past summers?' or: 'How likely will it be that the next decade will be warmer than past decades?' More specifically, a climate prediction might provide an answer to the question: 'What is the probability that temperature (in China, for instance) averaged over the next ten years will exceed the temperature in China averaged over the past 30 years?' Climate predictions do not provide forecasts of the detailed day-to-day evolution of future weather. Instead, they provide probabilities of long-term changes to the statistics of future climatic variables.

Weather forecasts, on the other hand, provide predictions of day-to-day weather for specific times in the future. They help to address questions like: 'Will it rain tomorrow?' Sometimes, weather forecasts are given in terms of probabilities. For example, the weather forecast might state that: 'the likelihood of rainfall in Apia tomorrow is 75%'.

To make accurate weather predictions, forecasters need highly detailed information about the current state of the atmosphere. The chaotic nature of the atmosphere means that even the tiniest error in the depiction of 'initial conditions' typically leads to inaccurate forecasts beyond a week or so. This is the so-called 'butterfly effect'.

Climate scientists do not attempt or claim to predict the detailed future evolution of the weather over coming seasons, years or decades. There is, on the other hand, a sound scientific basis for supposing that aspects of climate can be predicted, albeit imprecisely, despite the butterfly effect. For example, increases in long-lived atmospheric greenhouse gas concentrations tend to increase surface temperature in future decades. Thus, information from the past can and does help predict future climate.

Some types of naturally occurring so-called 'internal' variability can—in theory at least—extend the capacity to predict future climate. Internal climatic variability arises from natural instabilities in the climate system. If such variability includes or causes extensive, long-lived, upper ocean temperature anomalies, this will drive changes in the overlying atmosphere, both locally and remotely. The El Niño-Southern Oscillation phenomenon is probably the most famous example of this kind of internal variability. Variability linked to the El Niño-Southern Oscillation unfolds in a partially predictable fashion. The butterfly effect is present, but it takes longer to strongly influence some of the variability linked to the El Nino-Southern Oscillation.

Meteorological services and other agencies have exploited this. They have developed seasonal-to-interannual prediction systems that enable them to routinely predict seasonal climate anomalies with demonstrable predictive skill. The skill varies markedly from place to place and variable to variable. Skill tends to diminish the further the prediction delves into the future and in some locations there is no skill at all. 'Skill' is used here in its technical sense: it is a measure of how much greater the accuracy of a prediction is, compared with the accuracy of some typically simple prediction method like assuming that recent anomalies will persist during the period being predicted.

Weather, seasonal-to-interannual and decadal prediction systems are similar in many ways (e.g., they all incorporate the same mathematical equations for the atmosphere, they all need to specify initial conditions to kick-start

(continued on next page)

FAQ 11.1 (continued)

predictions, and they are all subject to limits on forecast accuracy imposed by the butterfly effect). However, decadal prediction, unlike weather and seasonal-to-interannual prediction, is still in its infancy. Decadal prediction systems nevertheless exhibit a degree of skill in *hindcasting* near-surface temperature over much of the globe out to at least nine years. A 'hindcast' is a prediction of a past event in which only observations prior to the event are fed into the prediction system used to make the prediction. The bulk of this skill is thought to arise from *external forcing*. 'External forcing' is a term used by climate scientists to refer to a forcing agent outside the climate system causing a change in the climate system. This includes increases in the concentration of long-lived greenhouse gases.

Theory indicates that skill in predicting decadal precipitation should be less than the skill in predicting decadal surface temperature, and hindcast performance is consistent with this expectation.

Current research is aimed at improving decadal prediction systems, and increasing the understanding of the reasons for any apparent skill. Ascertaining the degree to which the extra information from internal variability actually translates to increased skill is a key issue. While prediction systems are expected to improve over coming decades, the chaotic nature of the climate system and the resulting butterfly effect will always impose unavoidable limits on predictive skill. Other sources of uncertainty exist. For example, as volcanic eruptions can influence climate but their timing and magnitude cannot be predicted, future eruptions provide one of a number of other sources of uncertainty. Additionally, the shortness of the period with enough oceanic data to initialize and assess decadal predictions presents a major challenge.

Finally, note that decadal prediction systems are designed to exploit both externally forced and internally generated sources of predictability. Climate scientists distinguish between decadal predictions and decadal projections. Projections exploit only the predictive capacity arising from external forcing. While previous IPCC Assessment Reports focussed exclusively on projections, this report also assesses decadal prediction research and its scientific basis.

for both externally forced and internally generated components of the potential predictability of decadal means of surface air temperature in simulations of 21st century climate in CMIP3 model data are analysed in Boer (2011) and results based on CMIP5 model data are shown in Figure 11.2. Potential predictability of 5-year means for internally generated variability is found over extratropical oceans but is generally weak over land while that associated with the decadal change in the forced component is found in tropical areas and over some land areas.

Predictability studies of precipitation on long time scales are comparatively few. Jai and DelSole (2012) identify 'optimally predictable' fractions of internally generated temperature and precipitation variance over land on multi-year time scales in the control simulations of 10 models participating in CMIP5, with results that vary considerably from model to model. Boer and Lambert (2008) find little potential predictability for decadal means of precipitation in the internally generated variability of a collection of CMIP3 model control simulations other than over parts of the North Atlantic. This is also the case for the internally generated component of CMIP3 precipitation in 21st century climate change simulations in Boer (2011) although there is evidence of potential predictability for the forced component of precipitation mainly at higher latitudes and for longer time scales.

11.2.1.4 Summary

Predictability studies suggest that initialized climate forecasts should be able to provide more detailed information on climate evolution, over a few years to a decade, than is available from uninitialized climate simulations alone. Predictability results are, however, based mainly on climate model results and depend on the verisimilitude with which the models reproduce climate system behaviour (Chapter 9). There is evidence of multi-year predictability for both the internally generated and externally forced components of temperature over considerable portions of the globe with the first dominating at shorter and the second at longer time scales. Predictability for precipitation is based on fewer studies, is more modest than for temperature, and appears to be associated mainly with the forced component at longer time scales. Predictability can also vary from location to location.

11.2.2 Climate Prediction on Decadal Time Scales

11.2.2.1 Initial Conditions

A dynamical prediction consists of an ensemble of forecasts produced by integrating a climate model forward in time from a set of observation-based initial conditions. As the forecast range increases, processes in the ocean become increasingly important and the sparseness, non-uniformity and secular change in sub-surface ocean observations is a challenge to analysis and prediction (Meehl et al., 2009b, 2013d; Murphy et al., 2010) and can lead to differences among ocean analyses, that is, quantified descriptions of ocean initial conditions (Stammer, 2006; Keenlyside and Ba, 2010). Approaches to ocean initialization include (as listed in Table 11.1): assimilation only of SSTs to initialize the sub-surface ocean indirectly (Keenlyside et al., 2008;

Dunstone, 2010; Swingedouw et al., 2013); the forcing of the ocean model with atmospheric observations (e.g., Du et al., 2012; Matei et al., 2012b; Yeager et al., 2012) and more sophisticated alternatives based on fully coupled data assimilation schemes (e.g., Zhang et al., 2007a; Sugiura et al., 2009).

Dunstone and Smith (2010) and Zhang et al. (2010a) found an expected improvement in skill when sub-surface information was used as part of the initialization. Assimilation of atmospheric data, on the other hand, is expected to have little impact after the first few months (Balmaseda and Anderson, 2009). The initialization of sea ice, snow cover, frozen soil and soil moisture can potentially contribute to seasonal and sub-seasonal skill (e.g., Koster et al., 2010; Toyoda et al., 2011; Chevallier and Salas-Melia, 2012; Paolino et al., 2012), although an assessment of their benefit at longer time scales has not yet been determined.

11.2.2.2 Ensemble Generation

An ensemble can be generated in many different ways and a wide range of methods have been explored in seasonal prediction (e.g., Stockdale et al., 1998; Stan and Kirtman, 2008) but not yet fully investigated for decadal prediction (Corti et al., 2012). Methods being investigated include adding random perturbations to initial conditions, using atmospheric states displaced in time, using parallel assimilation runs (Doblas-Reyes et al., 2011; Du et al., 2012) and perturbing ocean initial conditions (Zhang et al., 2007a; Mochizuki et al., 2010). Perturbations leading to rapidly growing modes, common in weather forecasting, have also been investigated (Kleeman et al., 2003; Vikhliaev et al., 2007; Hawkins and Sutton, 2009, 2011; Du et al., 2012). The uncertainty associated with the limitations of a model's representation of the climate system may be partially represented by perturbed physics (Stainforth et al., 2005; Murphy et al., 2007) or stochastic physics (Berner et al., 2008), and applied to multi-annual and decadal predictions (Doblas-Reyes et al., 2009; Smith et al., 2010). Weisheimer et al. (2011) compare these three approaches in a seasonal prediction context.

The multi-model approach, which is used widely and most commonly, combines ensembles of predictions from a collection of models, thereby increasing the sampling of both initial conditions and model properties. Multi-model approaches are used across time scales ranging from seasonal–interannual (e.g., DEMETER; Palmer et al. (2004), to seasonal-decadal (e.g., Weisheimer et al., 2011; van Oldenborgh et al., 2012), in climate change simulation (e.g., IPCC, 2007, Chapter 10; Meehl et al., 2007b) and in the ENSEMBLES and CMIP5-based decadal predictions assessed in Section 11.2.3. A problem with the multi-model approach is tha inter-dependence of the climate models used in current forecast systems (Power et al. 2012; Knutti et al. 2013) is expected to lead to co-dependence of forecast error.

11.2.3 Prediction Quality

11.2.3.1 Decadal Prediction Experiments

Decadal predictions for specific variables can be made by exploiting empirical relationships based on past observations and expected physical relationships. Predictions of North Pacific Ocean temperatures have been achieved using prior wind stress observations (Schneider and Miller, 2001). Both global and regional predictions of surface temperature have been made based on projected changes in external forcing and the observed state of the natural variability at the start date (Lean and Rind, 2009; Krueger and von Storch, 2011; Ho et al., 2012a; Newman, 2013). Some of these forecast systems are also used as benchmarks to compare with the dynamical systems under development. Comparisons (Newman (2013) have shown that there is similarity in the temperature skill between a linear inverse method and the CMIP5 hindcasts, pointing at a similarity in their sources of skill. In the future, the combination of information from empirical and dynamical predictions might be explored to provide a unified and more skilful source of information.

Evidence for skilful interannual to decadal temperatures using dynamical models forced only by previous and projected changes in anthropogenic greenhouse gases (GHGs) and aerosols and natural variations in volcanic aerosols and solar irradiance is reported by Lee et al. (2006b), Räisänen and Ruokolainen (2006) and Laepple et al. (2008). Some attempts to predict the 10-year climate over regions have been done using this approach, and include assessments of the role of the internal decadal variability (Hoerling et al., 2011). To be clear, in the context of this report these studies are viewed as projections because no attempt is made to use observational estimates for the initial conditions. Essentially, an uninitialized prediction is synonymous with a projection. These projections or uninitialized predictions are referred to synonymously in the literature as 'NoInit,' or 'NoAssim', referring to the fact that no assimilated observations are used for the specification of the initial conditions.

Additional skill can be realized by initializing the models with observations in order to predict the evolution of the internally generated component and to correct the model's response to previously imposed forcing (Smith et al., 2010; Fyfe et al., 2011; Kharin et al., 2012; Smith et al., 2012). Again, to be clear, the assessment provided here distinguishes between predictions in which attempts are made to initialize the models with observations, and projections. See Box 11.1 and FAQ 11.1 for further details.

The ENSEMBLES project (van Oldenborgh et al., 2012), for example, has conducted a multi-model decadal retrospective prediction study, and the Coupled Model Intercomparison Project phase 5 (CMIP5) proposed a coordinated experiment that focuses on decadal, or near-term, climate prediction (Meehl et al., 2009b; Taylor et al., 2012). Prior to these initiatives, several pioneering attempts at initialized decadal prediction were made (Pierce et al., 2004; Smith et al., 2007; Troccoli and Palmer, 2007; Keenlyside et al., 2008; Pohlmann et al., 2009; Mochizuki et al., 2010). Results from the CMIP5 coordinated experiment (Taylor et al., 2012) are the basis for the assessment reported here.

Because the practice of decadal prediction is in its infancy, details of how to initialize the models included in the CMIP5 near-term experiment were left to the discretion of the modelling groups and are described in Meehl et al. (2013d) and Table 11.1. In CMIP5 experiments, volcanic aerosol and solar cycle variability are prescribed along the integration using observation-based values up to 2005, and assuming a climatological 11-year solar cycle and a background volcanic aerosol load in the future. These forcings are shared with CMIP5

historical runs (i.e., unintialized projections) started from pre-industrial control simulations, enabling an assessment of the impact of initialization. The specification of the volcanic aerosol load and the solar irradiance in the hindcasts gives an optimistic estimate of the forecast quality with respect to an operational prediction system, where no such future information can be used. Table 11.1 summarizes forecast systems contributing to, and the initialization methods used in, the CMIP5 near-term experiment.

The coordinated nature of the ENSEMBLES and CMIP5 experiments also offers a good opportunity to study *multi-model* ensembles (Garcia-Serrano and Doblas-Reyes, 2012; van Oldenborgh et al., 2012) as a means of sampling model uncertainty while some modelling groups have also investigated this using perturbed parameter approaches (Smith et al., 2010). The relative merit of the different approaches for decadal predictions has yet to be assessed.

When initialized with states close to the observations, models 'drift' towards their imperfect climatology (an estimate of the mean climate), leading to biases in the simulations that depend on the forecast time. The time scale of the drift in the atmosphere and upper ocean is, in most cases, a few years (Hazeleger et al., 2013a). Biases can be largely removed using empirical techniques a posteriori (Garcia-Serrano and Doblas-Reyes, 2012; Kharin et al., 2012). The bias correction or adjustment linearly corrects for model drift (e.g., Stockdale, 1997; Garcia-Serrano et al., 2012; Gangstø et al., 2013). The approach assumes that the model bias is stable over the prediction period (from 1960 onward in the CMIP5 experiment). This might not be the case if, for instance, the predicted temperature trend differs from the observed trend (Fyfe et al., 2011; Kharin et al., 2012). Figure 11.2 is an illustration of the time scale of the global SST drift, while at the same time showing the systematic error of several of the forecast systems contributing to CMIP5. It is important to note that the systematic errors illustrated here are

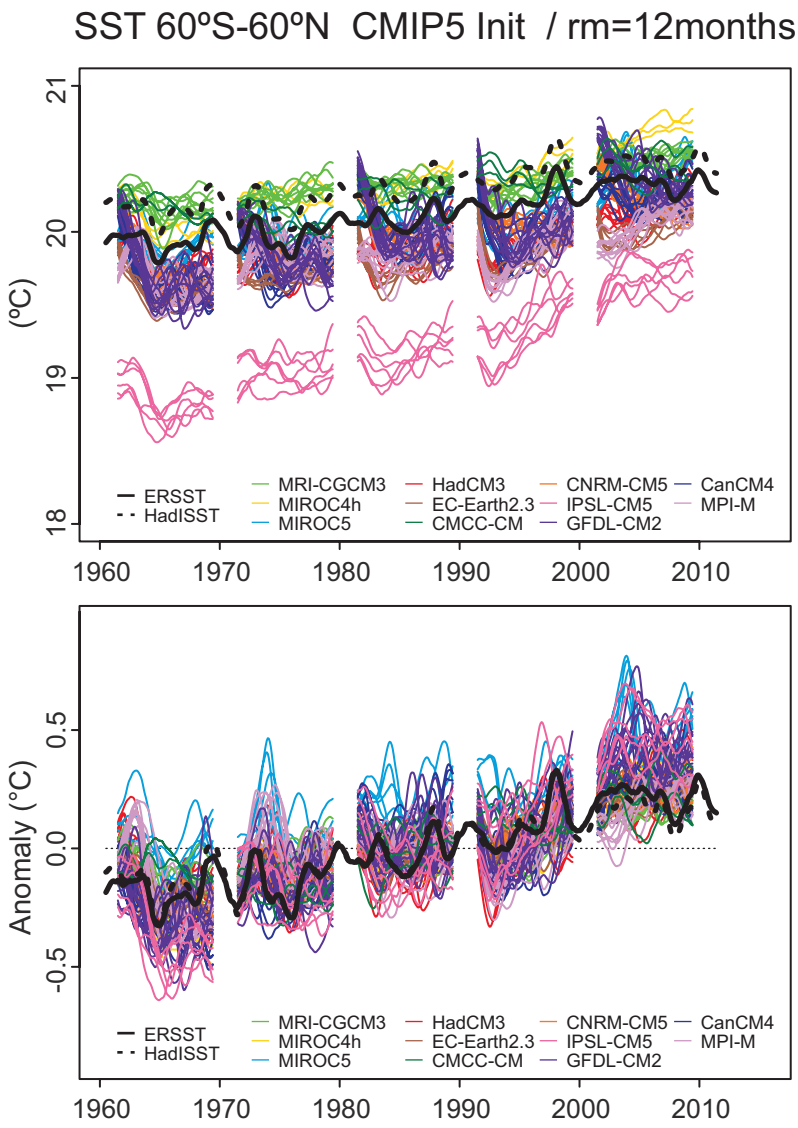

Figure 11.2 | Time series of global mean sea surface temperature from the (a) direct model output and (b) anomalies of the CMIP5 multi-model initialized hindcasts. Results for each forecast system are plotted with a different colour, with each line representing an individual member of the ensemble. Results for the start dates 1961, 1971, 1981, 1991 and 2001 are shown, while the model and observed climatologies to obtain the anomalies in (b) have been estimated using data from start dates every five years. The reference data (ERSST) is drawn in black. All time series have been smoothed with a 24-month centred moving average that filters out the seasonal cycle and removes data for the first and last years of each time series.

Table 11.1 | Initialization methods used in models that entered CMIP5 near-term experiments. (Figures 11.3 to 11.7 have been prepared using those contributions with asterisk on top of the modelling centre's name.).

common to both decadal prediction systems and climate-change projections. The bias adjustment itself is another important source of uncertainty in climate predictions (e.g., Ho et al., 2012b). There may be nonlinear relationships between the mean state and the anomalies, that are neglected in linear bias adjustment techniques. There are also difficulties in estimating the drift in the presence of volcanic eruptions.

It has been recognized that including as many initial states as possible in computing the drift and adjusting the bias is more desirable than a greater number of ensemble members per initial state (Meehl et al., 2013d), although increasing both is desirable to obtain robust forecast quality estimates. A procedure for bias adjustment following the technique outlined above has been recommended for CMIP5 (ICPO, 2011). A suitable adjustment depends also on there being a sufficient number of hindcasts for statistical robustness (Garcia-Serrano et al., 2012; Kharin et al., 2012).

To reduce the impact of the drift many of the early attempts at decadal prediction (Smith et al., 2007; Keenlyside et al., 2008; Pohlmann et al., 2009; Mochizuki et al., 2010) use an approach called anomaly initialization (Schneider et al., 1999; Pierce et al., 2004; Smith et al., 2007). The anomaly initialization approach attempts to circumvent model drift and the need for a time-varying bias correction. The models are initialized by adding observed anomalies to an estimate of the model mean climate. The mean model climate is subsequently subtracted from the predictions to obtain forecast anomalies. Sampling error in the estimation of the mean climatology affects the success of this approach. This is also the case for full-field initialization, although as anomaly initialisation is affected to a smaller degree by the drift, the sampling error is assumed to be smaller (Hazeleger et al., 2013a). The relative merits of anomaly versus full initialization are being quantified (Hazeleger et al., 2013a; Magnusson et al., 2013; Smith et al., 2013a), although no initialization method was found to be definitely better in terms of forecast quality. Another less widely explored alternative is dynamic bias correction in which multi-year monthly mean analysis increments are added during the integration of the ocean model (Wang et al., 2013). Figure 11.2 includes predictions performed with both full and anomaly initialization systems.

11.2.3.2 Forecast Quality Assessment

The quality of a forecast system is assessed by estimating, among others, the accuracy, skill and reliability of a set of hindcasts (Jolliffe and Stephenson, 2011). These three terms—accuracy, skill and reliability—are used here in a strict technical sense. A suite of measures needs to be considered, particularly when a forecast system are compared. The accuracy of a forecast system refers to the average distance/error between forecasts and observations. The skill score is a relative measure of the quality of the forecasting system compared to some benchmark or reference forecast (e.g., climatology or persistence). The reliability, which is a property of the specific forecast system, measures the trustworthiness of the predictions. Reliability measures how well the predicted probability distribution matches the observed relative frequency of the forecast event. Accuracy and reliability are aspects of forecast quality that can be improved by improving the individual forecast systems or by combining several of them into a multi-model prediction. The reliability can be improved by *a posteriori* corrections to model spread. Forecast quality can also be improved by unequal weighting (Weigel et al., 2010; DelSole et al., 2013), although this option has not been explored in decadal prediction to date, because a long training sample is required to obtain robust weights.

The assessment of forecast quality depends on the quantities of greatest interest to those who use the information. World Meteorological Organization (WMO)'s Standard Verification System (SVS) for Long-Range Forecasts (LRF) (WMO, 2002) outlines specifications for long-range (sub-seasonal to seasonal) forecast quality assessment. These measures are also described in Jolliffe and Stephenson (2011) and Wilks (2006). A recommendation for a deterministic metric for decadal climate predictions is the mean square skill score (MSSS), and for a probabilistic metric, the continuous ranked probability skill score (CRPSS) as described in Goddard et al. (2013) and Meehl et al. (2013d). For dynamical ensemble systems, a useful measure of the characteristics of an ensemble forecast system is spread. The relative spread can be described in terms of the ratio between the mean spread around the ensemble mean and the root mean square error (RMSE) of the ensemble-mean prediction, or spread-to-RMSE ratio. A ratio of 1 is considered a desirable feature for a Gaussian-distributed variable of a well-calibrated (i.e., reliable) prediction system (Palmer et al., 2006). The importance of using statistical inference in forecast quality assessments has been recently emphasized (Garcia-Serrano and Doblas-Reyes, 2012; Goddard et al., 2013). This is even more important when there are only small samples available (Kumar, 2009) and a small number of degrees of freedom (Gangstø et al., 2013). Confidence intervals for the scores are typically computed using either parametric or bootstrap methods (Lanzante, 2005; Jolliffe, 2007; Hanlon et al., 2013).

The skill of seasonal predictions can vary from generation to generation (Power et al. 1999) and from one generation of forecast systems to the next (Balmaseda et al., 1995). This highlights the possibility that the skill of decadal predictions might also vary from one period to another. Certain initial conditions might precede more predictable near-term states than other initial conditions, and this has the potential to be reflected in predictive skill assessments. However, the short length of the period available to initialize and verify the predictions makes the analysis of the variations in skill very difficult.

11.2.3.3 Pre-CMIP5 Decadal Prediction Experiments

Early decadal prediction studies found little additional predictive skill from initialization, over that due to changes in radiative forcing (RF), on global (Pierce et al., 2004) and regional scales (Troccoli and Palmer, 2007). However, neither of these studies considered more than two start dates. More comprehensive tests, which considered at least nine different start dates indicated temperature skill (Smith et al., 2007; Keenlyside et al., 2008; Pohlmann et al., 2009; Sugiura et al., 2009; Mochizuki et al., 2010; Smith et al., 2010; Doblas-Reyes et al., 2011; Garcia-Serrano and Doblas-Reyes, 2012; Garcia-Serrano et al., 2012; Kroger et al., 2012; Matei et al., 2012b; van Oldenborgh et al., 2012; Wu and Zhou, 2012; MacLeod et al., 2013). Moreover, this skill was enhanced by initialization (local increase in correlation of 0.1 to 0.3, depending on the system) mostly over the ocean, in particular over the North Atlantic and subtropical Pacific oceans. Regions with skill

improvements from initialization for precipitation are small and rarely statistically significant (Goddard et al., 2013).

11.2.3.4 Coupled Model Intercomparison Project Phase 5 Decadal Prediction Experiments

Indices of global mean temperature, the Atlantic Multi-decadal Variability (AMV; (Trenberth and Shea, 2006)) and the Inter-decadal Pacific Oscillation (IPO; Power et al., 1999) or Pacific Decadal Oscillation (PDO) are used as benchmarks to assess the ability of decadal forecast systems to predict multi-annual averages of climate variability (Kim et al., 2012; van Oldenborgh et al., 2012; Doblas-Reyes et al., 2013; Goddard et al., 2013; see also Figure 11.3). Initialized predictions of global mean surface air temperature (GMST) for the following year are now being performed in almost-real time (Folland et al., 2013).

Non-initialized predictions (or projections) of the global mean temperature are statistically significantly skilful for most of the forecast ranges considered (*high confidence*), due to the almost monotonic increase in temperature, pointing to the importance of the time-varying RF (Murphy et al., 2010; Kim et al., 2012). This leads to a high (above 0.9) correlation of the ensemble mean prediction that varies very as a function of forecast lead time. This holds whether the changes in the external forcing (i.e., changes in natural and/or anthropogenic atmospheric composition) are specified (i.e., CMIP5) or are projected (ENSEMBLES). The skill of the multi-annual global mean surface temperature improves with initialization, although this is mainly evidenced when the accuracy is measured in terms of the RMSE (Doblas-Reyes et al., 2013). An improved prediction of global mean surface temperature is evidenced by the closer fit of the initialized predictions during the 21st century (Figure 11.3; Meehl and Teng, 2012; Doblas-Reyes et al., 2013; Guemas et al., 2013; Box 9.2). The impact of initialization is seen as a better representation of the phase of the internal variability, in particular in increasing the upper ocean heat content (Meehl et al., 2011) and in terms of a correction of the model's forced response.

The AMV (Chapter 14) has important impacts on temperature and precipitation over land (Li and Bates, 2007; Li et al., 2008; Semenov et al., 2010). The AMV index shows a large fraction of its variability on decadal time scales and has multi-year predictability (Murphy et al., 2010; Garcia-Serrano and Doblas-Reyes, 2012). The AMV has been connected to multi-decadal variability of Atlantic tropical cyclones (Goldenberg et al., 2001; Zhang and Delworth, 2006; Smith et al., 2010; Dunstone et al., 2011). Figure 11.3 shows that the CMIP5 multi-model ensemble mean has skill on multi-annual time scales, the skill being generally larger than for the single-model forecast systems (Garcia-Serrano and Doblas-Reyes, 2012; Kim et al., 2012). The skill of the AMV index improves with initialization (*high confidence*) for the early forecast ranges. In particular, the RMSE is substantially reduced (indicating improved skill) with initialization for the AMV. The positive correlation of the non-initialized AMV predictions is consistent with the view that part of the recent variability is due to external forcings (Evan et al., 2009; Ottera et al., 2010; Chang et al., 2011; Booth et al., 2012; Garcia-Serrano et al., 2012; Terray, 2012; Villarini and Vecchi, 2012; Doblas-Reyes et al., 2013).

Pacific decadal variability is associated with potentially important climate impacts, including rainfall over America, Asia, Africa and Australia (Power et al., 1999; Deser et al., 2004; Seager et al., 2008; Zhu et al., 2011; Li et al., 2012). The combination of Pacific and Atlantic variability and climate change is an important driver of multi-decadal USA drought (McCabe et al., 2004; Burgman et al., 2010) including key events like the American dustbowl of the 1930s (Schubert et al., 2004). van Oldenborgh et al. (2012) reported weak skill in hindcasting the IPO in the ENSEMBLES multi-model. Doblas-Reyes et al. (2013) show that the ensemble-mean skill of the ENSEMBLES multi-model IPO is not statistically significant at the 95% level and shows no clear impact of the initialization, in agreement with the predictability study of Meehl et al. (2010). On the other hand, case studies suggest that there might be some initial states that can produce skill in predicting IPO-related decadal variability for some time periods (e.g., Chikamoto et al., 2012b; Meehl and Arblaster, 2012; Meehl et al., 2013a).

The higher AMV and global mean temperature skill of the CMIP5 predictions with respect to the ENSEMBLES hindcasts (van Oldenborgh et al., 2012; Goddard et al., 2013) might be partly due to the CMIP5 multi-model using specified instead of projected aerosol loading (especially the volcanic aerosol) and solar irradiance variations during the simulations. As these forcings cannot be specified in a real forecast setting, ENSEMBLES offers an estimate of the skill closer to what could be expected from a real-time forecast system such as the one described in (Smith et al., 2013a). The use of correct forcings nevertheless allows a more powerful test of the effect of initialization on the ability of models to reproduce past observations.

Near-term prediction systems have significant skill for temperature over large regions (Figure 11.4), especially over the oceans (Smith et al., 2010; Doblas-Reyes et al., 2011; Kim et al., 2012; Matei et al., 2012b; van Oldenborgh et al., 2012; Hanlon et al., 2013). It has been shown that a large part of the skill corresponds to the correct representation of the long-term trend (*high confidence*) as the skill decreases substantially after an estimate of the long-term trend is removed from both the predictions and the observations (e.g., Corti et al., 2012; van Oldenborgh et al., 2012; MacLeod et al., 2013). Robust skill increase due to initialization (Figure 11.4) is limited to areas of the North Atlantic, the Indian Ocean and the southeast Pacific (*high confidence*) (Doblas-Reyes et al., 2013), in agreement with previous results (Pohlmann et al., 2009; Smith et al., 2010; Mochizuki et al., 2012) and predictability estimates (Branstator and Teng, 2012). Similar results have been found in several individual forecast systems (e.g., Muller et al., 2012; Bellucci et al., 2013). However, the impact of initialization on the skill in those regions, though robust (as shown by the agreement between the different CMIP5 systems) is small and not statistically significant with 90% confidence.

The improvement in retrospective North Atlantic variability predictions from initialization (Smith et al., 2010; Dunstone et al., 2011; Garcia-Serrano et al., 2012; Hazeleger et al., 2013b) suggests that internal variability was important to North Atlantic variability during the past few decades. However, the interpretation of the results is complicated by the fact that the impact on skill varies slightly with the forecast quality measure used (Figure 11.3; Doblas-Reyes et al., 2013). This has been attributed to, among other things, the different impact of the predicted local trends on the scores used (Goddard et al., 2013). Skill in hindcasts of subpolar Atlantic temperature, which is evident in Figure 11.4, is

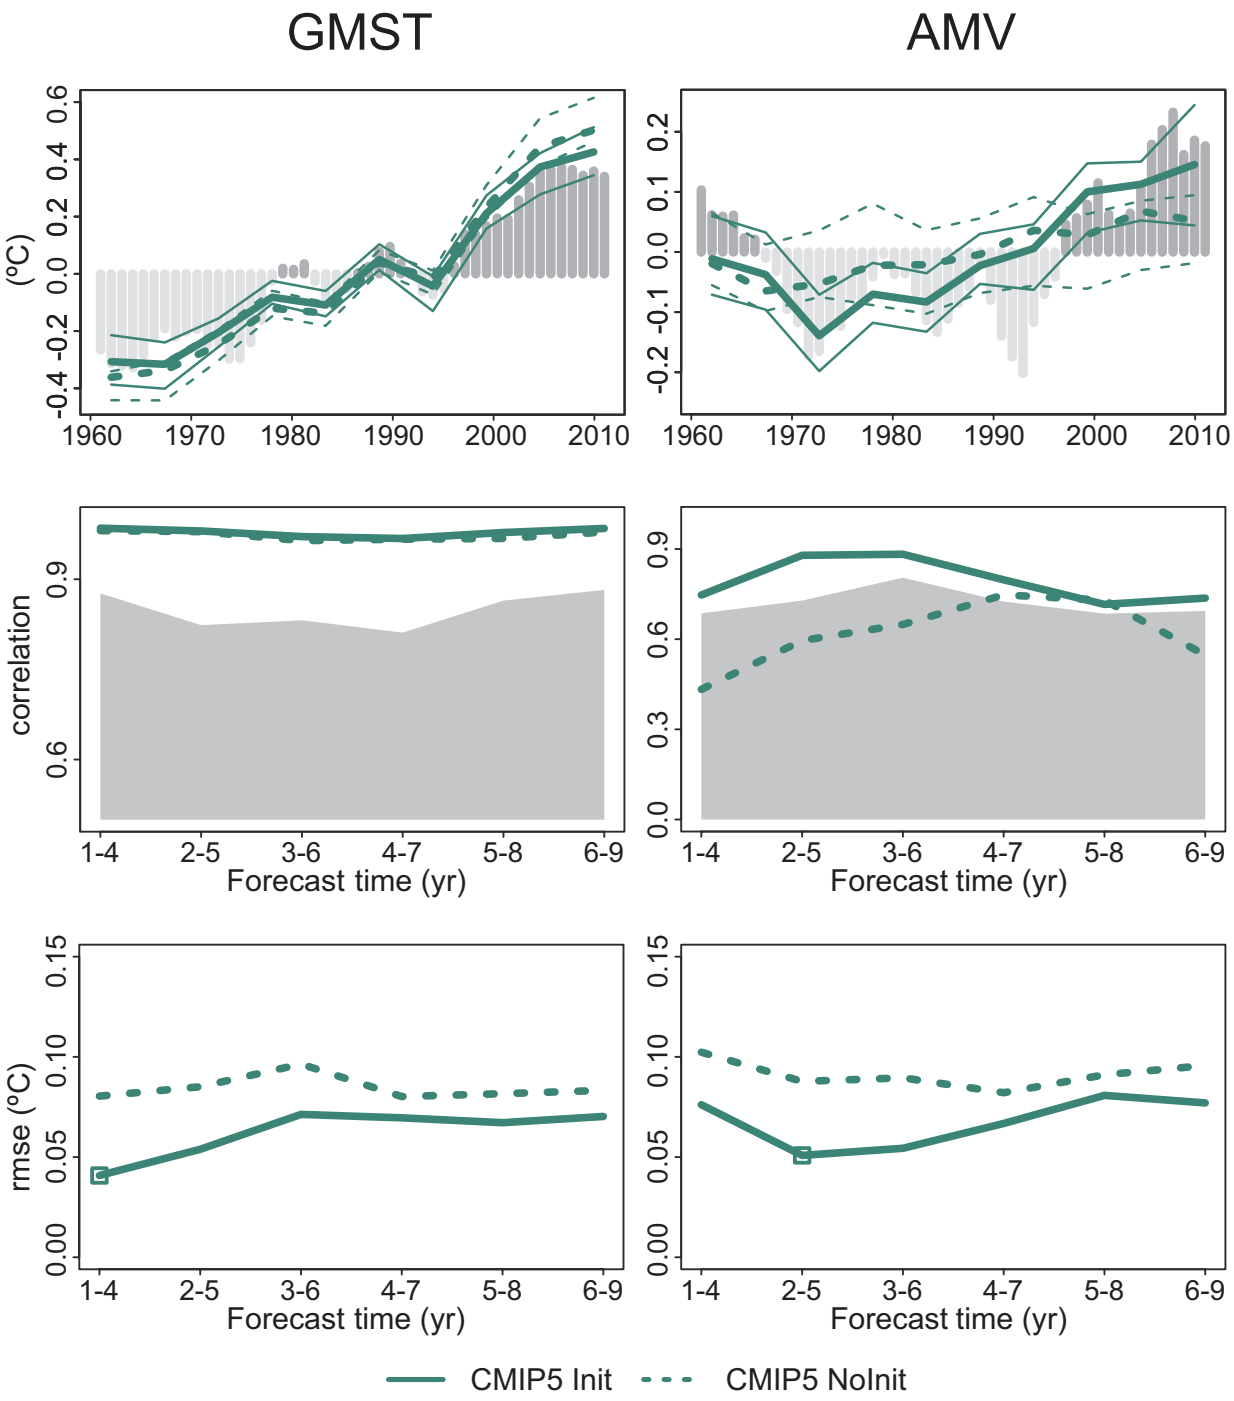

Figure 11.3 | Decadal prediction forecast quality of two climate indices. (Top row) Time series of the 2- to 5-year average ensemble-mean initialized hindcast anomalies and the corresponding non-initialized experiments for two climate indices: global mean surface temperature (GMST, left) and the Atlantic multi-decadal variability (AMV, right). The observational time series, Goddard Institute of Space Studies (GISS) GMST and Extended Reconstructed Sea Surface Temperature (ERSST) for the AMV, are represented with dark grey (positive anomalies) and light grey (negative anomalies) vertical bars, where a 4-year running mean has been applied for consistency with the time averaging of the predictions. Predicted time series are shown for the CMIP5 Init (solid) and NoInit (dotted) simulations with hindcasts started every 5 years over the period 1960–2005. The lower and upper quartile of the multi-model ensemble are plotted using thin lines. The AMV index was computed as the SST anomalies averaged over the region Equator to 60°N and 80°W to 0°W minus the SST anomalies averaged over 60°S to 60°N. Note that the vertical axes are different for each time series. (Middle row) Correlation of the ensemble mean prediction with the observational reference along the forecast time for 4-year averages of the three sets of CMIP5 hindcasts for Init (solid) and NoInit (dashed). The one-sided 95% confidence level with a *t* distribution is represented in grey. The effective sample size has been computed taking into account the autocorrelation of the observational time series. A two-sided *t* test (where the effective sample size has been computed taking into account the autocorrelation of the observational time series) has been used to test the differences between the correlation of the initialized and non-initialized experiments, but no differences where found statistically significant with a confidence equal or higher than 90%. (Bottom row) Root mean square error (RMSE) of the ensemble mean prediction along the forecast time for 4-year averages of the CMIP5 hindcasts for Init (solid) and NoInit (dashed). A two-sided *F* test (where the effective sample size has been computed taking into account the autocorrelation of the observational time series) has been used to test the ratio between the RMSE of the Init and NoInit, and those forecast times with differences statistically significant with a confidence equal or higher than 90% are indicated with an open square. (Adapted from Doblas-Reyes et al., 2013.)

improved more by initialization than is skill in hindcasting sub-tropical Atlantic temperature (Garcia-Serrano et al., 2012; Robson et al., 2012; Hazeleger et al., 2013b). This is relevant because the sub-polar branch of the AMV is a source of skill for multi-year North Atlantic tropical storm frequency predictions (Smith et al., 2010). Vecchi et al. (2013) argued that the nominal improvement in multi-year forecasts of North Atlantic hurricane frequency was mainly due to persistence.

Sugiura et al. (2009) reported on skill in hindcasting the Pacific Decadal Oscillation (PDO) in their forecast system. They ascribed the skill to the interplay between Rossby waves and a clockwise propagation of ocean heat content anomalies along the Kuroshio–Oyashio extension and subtropical subduction pathway. However, as Figure 11.4 shows, the Pacific Ocean has the lowest temperature skill overall, with no consistent impact from initialization. The central North Pacific has zero or negative skill, which may be due to the relatively large amplitude of the interannual variability when compared to the long-term trend; the overall failure to predict the largest warming events (Guémas et al., 2012) beyond a few months; and differences (compared to AMV) in how surface temperature and upper ocean heat content interact for the PDO (Mochizuki et al., 2010; Chikamoto et al., 2012a; Mochizuki et al., 2012). There is a robust loss of skill due to initialization in the CMIP5 predictions over the equatorial Pacific (Doblas-Reyes et al., 2013) that has not been adequately explained.

The AMV is thought to be related to the AMOC (Knight et al., 2005). An assessment of the impact of observing systems on AMOC predictability indicates that the recent dense observations of oceanic temperature and salinity are crucial to constraining the AMOC in one model Zhang et al. (2007a). The observing system representative of the pre-2000s was not as effective, indicating that inadequate observations in the past might also limit the impact of initialization on the predictions. This has been confirmed by Pohlmann et al. (2013) using decadal predictions, where they also find a positive impact from initialization that agrees with Hazeleger et al. (2013b). Assessments of the skill of prediction systems to hindcast past variability in the AMOC have been attempted (Pohlmann et al., 2013; Swingedouw et al., 2013) although direct measures of the AMOC are far too short to underpin a reliable estimate of skill, and longer histories are poorly known (Matei et al., 2012a; Vecchi et al., 2012). There is *very low confidence* in current estimates of the skill of the AMOC hindcasts. Sustained ocean observations, such as Argo, a broad global array of temperature/salinity profiling floats, and Rapid Climate Change-Meridional Overturning Circulation and Heatflux Array (RAPID-MOCHA), will be needed to build a capability to reliably predict the AMOC (Srokosz et al., 2012).

Climate prediction is, by nature, probabilistic. Probabilistic predictions are expected to be skilful, but also reliable. Decadal predictions should be evaluated on the basis of whether they give an accurate estimation of the relative frequency of the predicted outcome. This question can be addressed using, among other tools, attributes diagrams (Mason, 2004). They measure how closely the forecast probabilities of an event correspond to the mean probability of observing the event. They are based on a discrete binning of many forecast probabilities taken over a given geographical region. Figure 11.5 illustrates the CMIP5 multi-model Init and NoInit attributes diagrams for predictions of both the global and North Atlantic SSTs to be in the lower tercile (where the tercile threshold has been estimated separately for the predictions and the observations). The diagrams are constructed using predictions for each grid point over the corresponding area. For perfect reliability the forecast probability and the frequency of occurrence should be equal, and the plotted points should lie on the diagonal (solid black line in the figure). When the line joining the bullets (the reliability curve) has positive slope it indicates that as the forecast probability of the event increases, so does the chance of observing the event. The predictions therefore can be considered as moderately reliable. However, if the slope of the curve is less than the slope of the diagonal, then the forecast system is overconfident. If the reliability curve is mainly horizontal, then the frequency of occurrence of the event does not depend on the forecast probabilities and the predictions contain no more information than a random guess. An ideal forecast should have a good resolution whilst retaining reliability, that is, probability forecasts should be both sharp and reliable.

In agreement with Corti et al. (2012), CMIP5 multi-model surface temperature predictions are more reliable for the North Atlantic than when considered over the global oceans, and have a tendency to be overconfident particularly for the global oceans (*medium confidence*). This means that the multi-model ensemble spread should not be considered as a robust measure of the actual uncertainty, at least for multi-annual averages. The attributes diagrams already take into account the systematic error in the simulated variability by estimating separately the event thresholds for the predictions and the observational reference. For the North Atlantic, initialization improves the reliability of the predictions, which translates into an increase of the Brier skill score, the probabilistic skill measure with respect to a naïve climatological prediction (which is reliable, but not skilful) used to aggregate the information in the attributes diagram. However, the uncertainty associated with these estimates is not negligible. This is due mainly to the small sample of start dates, which has the consequence that the number of predictions with a given probability is small to give a robust estimate of the observed relative frequency (Brocker and Smith, 2007). In addition to this, there are biases in the reliability diagram itself (Ferro and Fricker, 2012). These results suggest that the multi-model ensemble should be used with care when estimating probability forecasts or the uncertainty of the mean predictions. Given that the models used for the dynamical predictions are the same as those used for the projections, this verification also provides useful information for the assessment of the projections (cf. Box 11.2).

The skill in hindcasting precipitation over land (Figure 11.6) is much lower than the skill in hindcasting temperature over land. This is consistent with predictability studies discussed previously (e.g., Box 11.1) (*high confidence*). Several regions, especially in the Northern Hemisphere (NH) and West Africa (Gaetani and Mohino, 2013), have skill but these regions are not statistically significant with a 95% confidence level. The positive skill in hindcasting precipitation can be attributed mostly to variable RF (*high confidence*) as initialization improves the skill very little (Goddard et al., 2013). The areas with positive skill agree with those where the precipitation trends of multi-annual averages are the largest (Doblas-Reyes et al., 2013). The skill in areas like West Africa might be associated with the positive AMV skill, as the AMV drives interannual variability in precipitation over this region (van Oldenborgh et al., 2012).

The small amount of statistically significant differences found between the initialized and non-initialized experiments does not necessarily mean that the impact of the initialization does not have a physical basis. A comparison of the global mean temperature and AMV forecast quality using 1- and 5-year intervals between start dates (Garcia-Serrano et al., 2012) suggests that, although a five-year interval sampling allows an estimate of the level of skill, local maxima as a function of forecast time might well be due to poor sampling of the start dates (Garcia-Serrano and Doblas-Reyes, 2012; Kharin et al., 2012; Doblas-Reyes et al., 2013; Goddard et al., 2013). Several signals, such as the

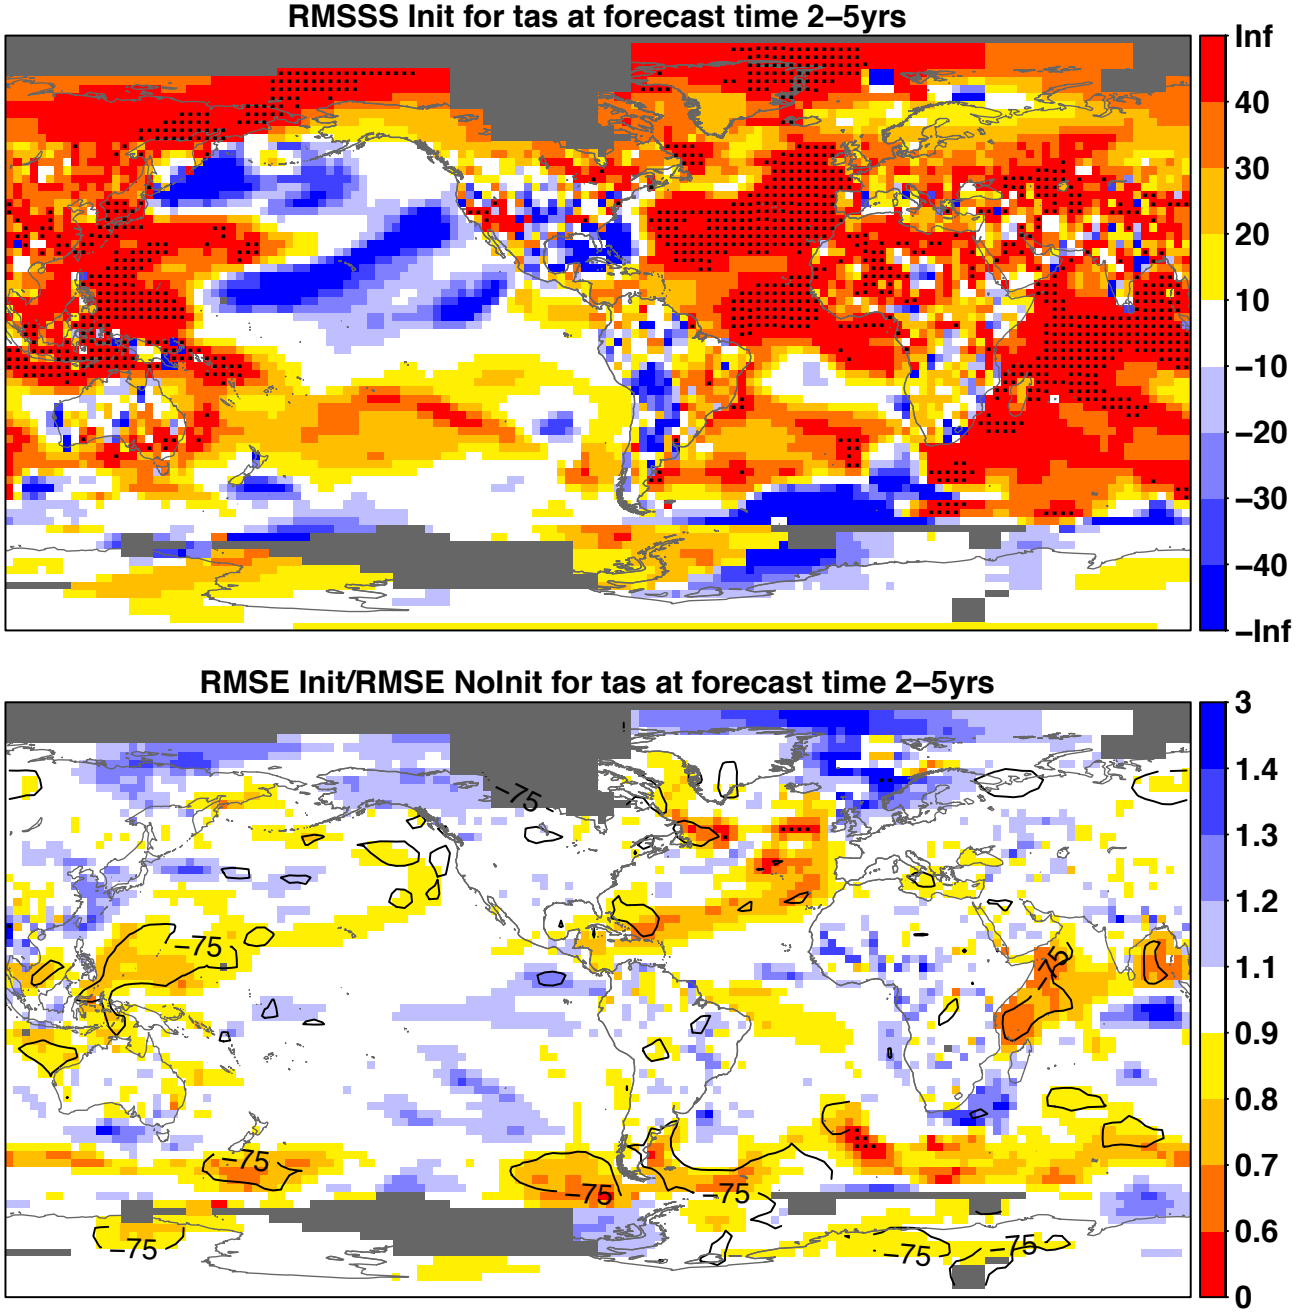

Figure 11.4 | (a) Root mean square skill score of the near surface air temperature forecast quality for the forecast time 2 to 5 years from the multi-model ensemble mean of the CMIP5 Init experiment with 5-year interval between start dates over the period 1960–2005. A combination of temperatures from Global Historical Climatology Network/Climate Anomaly Monitoring System (GHCN/CAMS) air temperature over land, Extended Reconstructed Sea Surface Temperature (ERSST) and Goddard Institute of Space Studies Surface Temperature Analysis (GISTEMP) 1200 over the polar areas is used as a reference. Black dots correspond to the points where the skill score is statistically significant with 95% confidence using a one-sided *F*-test taking into account the autocorrelation of the observation minus prediction time series. (b) Ratio between the root mean square error of the ensemble mean of Init and NoInit. Dots are used for the points where the ratio is significantly above or below 1, with 90% confidence using a two-sided *F*-test taking into account the autocorrelation of the observation minus prediction time series. Contours are used for areas where the ratio of at least 75% of the single forecast systems is either above or below one agreeing with the value of the ratio in the multi-model ensemble. Poorly observationally sampled areas are masked in grey. The original model data have been bilinearly interpolated to the observational grid. The ensemble mean of each forecast system has been estimated before computing the multi-model ensemble mean. (Adapted from Doblas-Reyes et al., 2013.)

skill improvement for temperature over the North Atlantic, are robust in the sense that it is found in more than 75% of forecast system. However, it is difficult to obtain statistical significance with these limited samples. The low start date sampling frequency is one of the limitations of the core CMIP5 near-term prediction experiment, the other one being the short length of the period of study, limited by the availability of observational data. Results estimated with yearly start dates are more robust than with a 5-year start date frequency. However, even with 1-year start date frequency, the impact of the initialization is similar. The spatial distribution of the skill does not change substantially with the different start date frequency. The skill and the initialization impact are both slightly reduced in the results with yearly start dates, but at the same time the spatial variability is substantially reduced.

The CMIP5 multi-model overestimates the spread of the multi-annual average temperature (Doblas-Reyes et al., 2013). Figure 11.7 shows the ratio of the spread around the ensemble mean prediction and the RMSE of the ensemble mean prediction of Init and NoInit, which in a well-calibrated system is expected to be close to 1. However, the ratio is overestimated over the North Atlantic, the Indian Ocean and the Arctic, and underestimated over the North Pacific and most continental areas, suggesting that the CMIP5 systems do not discriminate

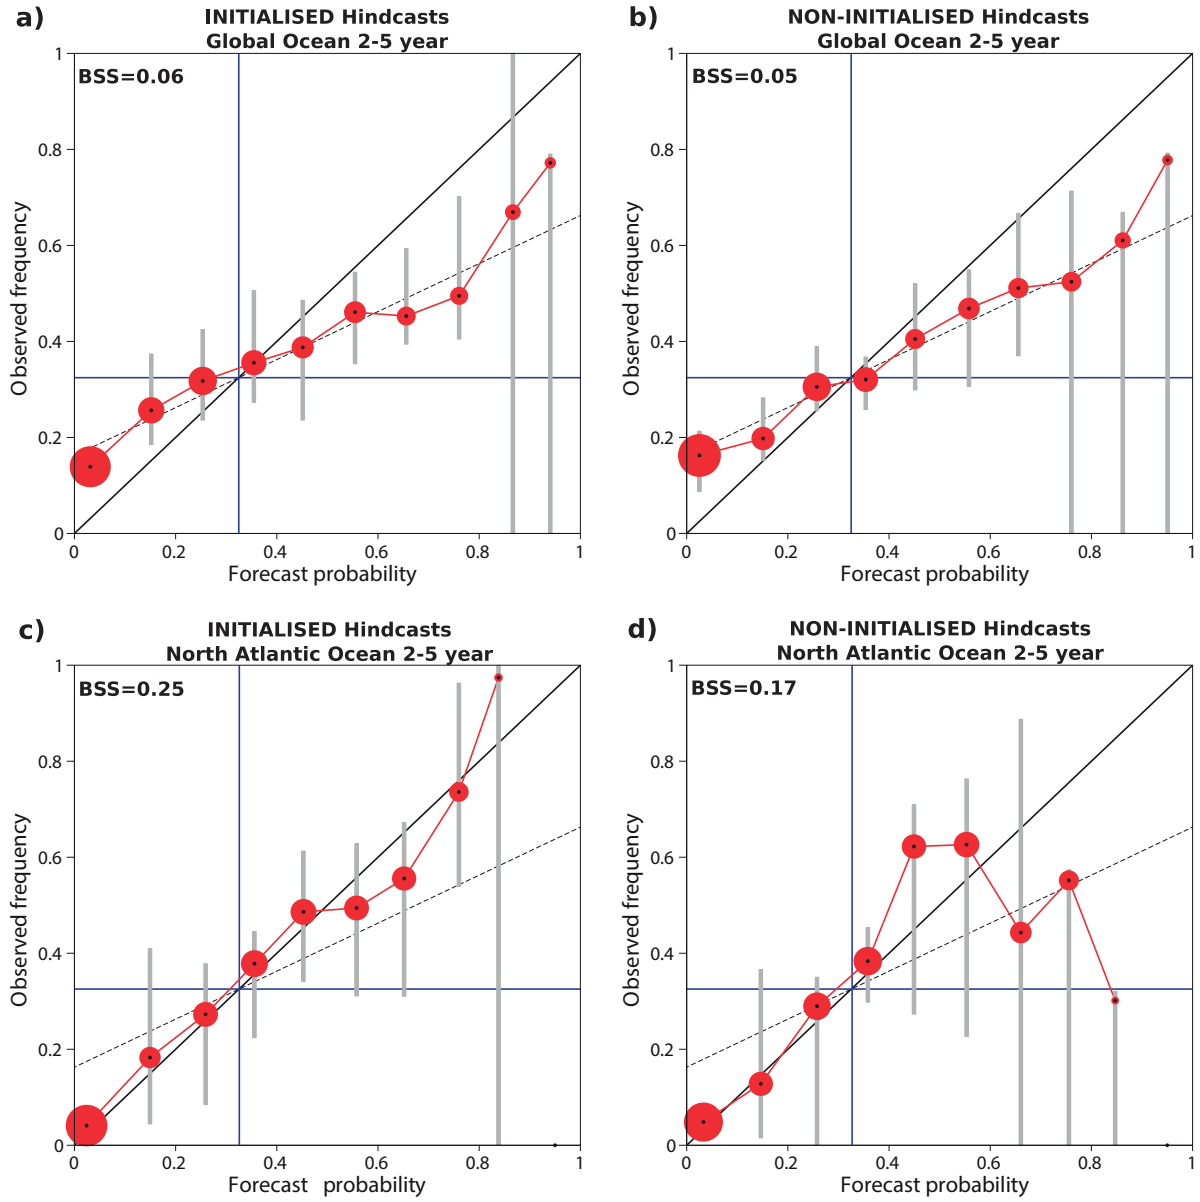

Figure 11.5 | Attributes diagram for the CMIP5 multi-model decadal initialized (a and c) and non-initialized (b and d) hindcasts for the event 'surface air temperature anomalies below the lower tercile over (a) and (b) the global oceans (60°N to 60°S) and (c) and (d) the North Atlantic (87.5°N to 30°N, 80°W to 10°W) for the forecast time 2 to 5 years. The red bullets in the figure correspond to the number of probability bins (10 in this case) used to estimate forecast probabilities. The size of the bullets represents the number of forecasts in a specific probability category and is a measure of the sharpness (or variance of the forecast probabilities) of the predictions. The blue horizontal and vertical lines indicate the climatological frequency of the event in the observations and the mean forecast probability, respectively. Grey vertical bars indicate the uncertainty in the observed frequency for each probability category estimated at 95% level of confidence with a bootstrap resampling procedure based on 1000 samples. The longer the bars, the more the vertical position of the bullets may change as new hindcasts become available. The black dashed line separates skilful from unskilled regions in the diagram in the Brier skill score sense. The Brier skill score with respect to the climatological forecast is drawn in the top left corner of each panel. (Adapted from Corti et al., 2012.)

between the regions where the spread should be reduced according to the RMSE level in the area. These results are found for both the Init and NoInit ensembles and agree with the overconfidence of the probability forecasts shown in Figure 11.6 (Corti et al., 2012). The spread overestimation also agrees with the results found for the indices illustrate in Figure 11.3 (Doblas-Reyes et al., 2013). The spread overestimation points to the need for a careful interpretation of current ensemble and probabilistic climate information for climate adaptation and services.

The skill of extreme daily temperature and precipitation in multi-annual time scales has also been assessed (Eade et al., 2012; Hanlon et al., 2013). There is little improvement in skill with the initialization beyond

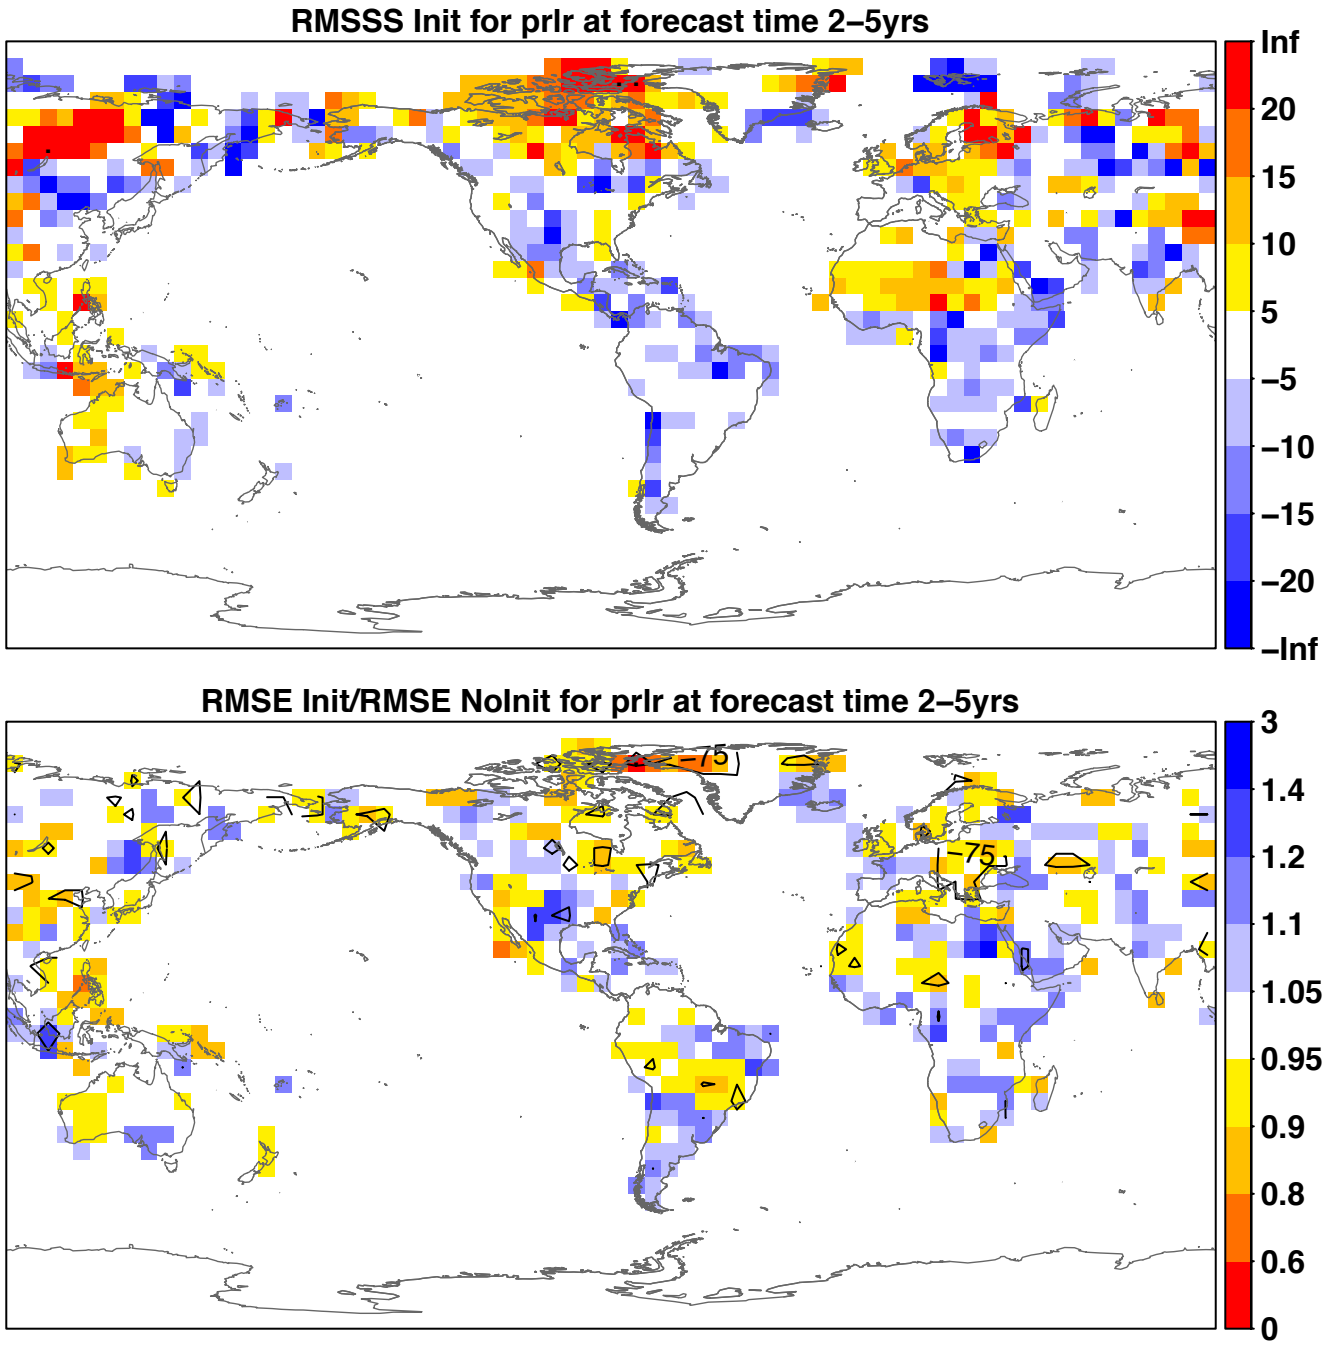

Figure 11.6 | (a) Root mean square skill score for precipitation hindcasts for the forecast time 2 to 5 years from the multi-model ensemble mean of the CMIP5 Init experiment with 5-year interval between start dates over the period 1960–2005. Global Precipitation Climatology Centre (GPCC) precipitation is used as a reference. Black dots correspond to the points where the skill score is statistically significant with 95% confidence using a one-sided *F*-test taking into account the autocorrelation of the observation minus prediction time series. (b) Ratio between the root mean square error of the ensemble mean of Init and NoInit. Dots are used for the points where the ratio is significantly above or below one with 90% confidence using a two-sided *F*-test taking into account the autocorrelation of the observation minus prediction time series. Contours are used for areas where the ratio of at least 75% of the single forecast systems is either above or below 1, agreeing with the value of the ratio in the multi-model ensemble. The model original data have been bilinearly interpolated to the observational grid. The ensemble mean of each forecast system has been estimated before computing the multi-model ensemble mean. (Adapted from Doblas-Reyes et al., 2013.)

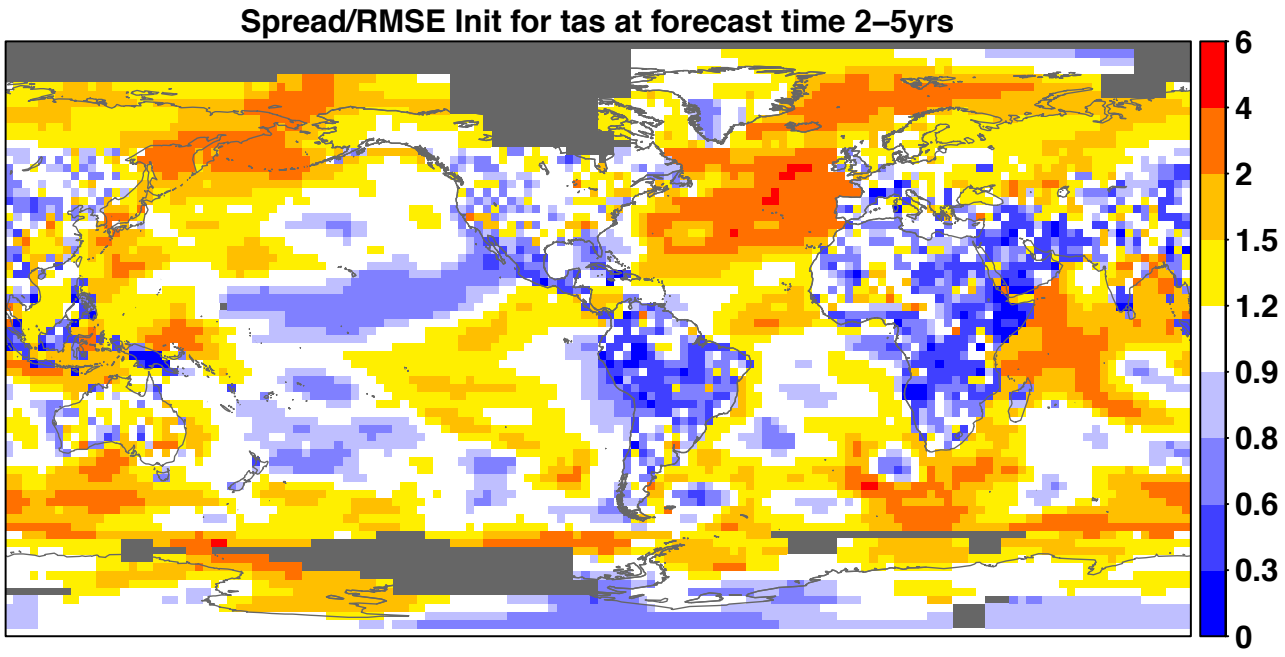

Figure 11.7 | Ratio between the surface temperature spread around the ensemble mean and the root mean square error (RMSE) of the ensemble-mean prediction of Init and NoInit for the forecast time 2 to 5 years with 5-year interval between start dates over the period 1960–2005. A combination of temperatures from Global Historical Climatology Network/Climate Anomaly Monitoring System (GHCN/CAMS) air temperature over land, Extended Reconstructed Sea Surface Temperature (ERSST) v3b over sea and Goddard Institute of Space Studies Surface Temperature Analysis (GISTEMP) 1200 over the polar areas is used as a reference to compute the RMSE. (Adapted from Doblas-Reyes et al., 2013.)

the first year, suggesting that skill then arises largely from the varying external forcing. The skill for extremes is generally similar to, but slightly lower than, that for the mean.

Responding to the increases in decadal skill in certain regions due to initialization, a coordinated quasi-operational decadal prediction initiative has been organized (Smith et al., 2013b). The forecast systems participating in the initiative are based on those of CMIP5 and have been evaluated for forecast quality. Statistical predictions are also included in the initiative. The most recent forecast shows (compared to the projections) substantial warming of the north Atlantic subpolar gyre, cooling of the north Pacific throughout the next decade and cooling over most land and ocean regions and in the global average out to several years ahead. However, in the absence of explosive or frequent volcanic eruptions, global surface temperature is predicted to continue to rise and, to a certain degree, recover from the reduced rate of warming (see Box 9.2).

11.2.3.5 Realizing Potential

Although idealized model experiments show considerable promise for predicting internal variability, realizing this potential is a challenging task. There are three main hurdles: (1) the limited availability of data to initialize and verify predictions, (2) limited progress in initialization techniques for decadal predictions and (3) dynamical model shortcomings that require validating how the simulated variance compares with the observed variance.

It is expected that the availability of temperature and salinity data in the top 2 km of the ocean through the enhanced global deployment of Argo floats will give a step change in our ability to initialize and predict ocean heat and density anomalies (Zhang et al., 2007a; Dunstone and Smith, 2010). Another important advancement is the availability of highly accurate altimetry data, made especially useful after the launching of TOPography EXperiment (TOPEX)/Poseidon in 1992. Argo and altimeter data became available only in 2000 and 1992 respectively, so an accurate estimate of their impact on real forecasts has to wait (Dunstone and Smith, 2010). In all cases, both the length of the observational data sets and the reduced coverage of the data available, especially before 2000, are serious limitations to obtain robust estimates of forecast quality.

Improved initialization of other aspects such as sea ice, snow cover, frozen soil and soil moisture, may also have potential to contribute to predictive skill beyond the seasonal time scale. This could be investigated, for example by using measurements of soil moisture from the Soil Moisture and Ocean Salinity (SMOS) satellite launched in 2009, or by initializing sea ice thickness with observations from the CryoSat-2 satellite launched in 2010. Along the same line, understanding the links between the initialization and the correct prediction of both the internal and external variability should help improving forecast quality (Solomon et al., 2011).

Many of the current decadal prediction systems use relatively simple initialization schemes and do not adopt fully coupled initialization/ensemble generation schemes. Assimilation schemes offer opportunities for fully coupled initialization including assimilation of variables such as sea ice, snow cover and soil moisture, although they present technically and scientifically challenging problems. This approach has been tested in schemes like four-dimensional variational data assimilation (4DVAR; Sugiura et al., 2008) and the ensemble Kalman filter (Keppenne et al., 2005; Zhang et al., 2007a).

Bias correction is used to reduce the effects of model drift, but the nonlinearity in the climate system (e.g., Power (1995) might limit the effectiveness of bias correction and thereby reduce forecast quality. Understanding and reducing both drift and systematic errors is important (Palmer and Weisheimer, 2011), as it is also for seasonal-to-interannual climate prediction and for climate change projections. While improving models is the highest priority, efforts to quantify the degree of interference between model bias and predictive signals should not be overlooked.

11.3 Near-term Projections

11.3.1 Introduction

In this section the outlook for global and regional climate up to mid-century is assessed, based on climate model projections. In contrast to the predictions discussed in Section 11.2, these projections are not initialized using observations; instead, they are initialized from historical simulations of the evolution of climate from pre-industrial conditions up to the present. The historical simulations are forced by estimates of past anthropogenic and natural climate forcing agents, and the projections are obtained by forcing the models with scenarios for future climate forcing agents. Major use is made of the CMIP5 model experiments forced by the Representative Concentration Pathway (RCP) scenarios discussed in Chapters 1 and 8. Projections of climate change in this and subsequent chapters are expressed relative to the reference period: 1986–2005. In this chapter most emphasis is given to the period 2016–2035, but some information on changes projected before and after this period (up to mid-century) is also provided. Longer-term projections are assessed in Chapters 12 and 13.

Key assessment questions addressed in this section are: *What is the externally forced signal of near-term climate change, and how large is it compared to natural internal variability?* From the point of view of climate impacts, the absolute magnitude of climate change may in some instances be less important than the magnitude relative to the local level of natural internal variability. Because many systems are naturally adapted to a background level of variability, it may be changes that move outside of this range that are most likely to trigger impacts that are unprecedented in the recent past (e.g., Lobell and Burke (2008) for crops).

An important conclusion of the AR4 (Section 10.3.1) was that near-term climate projections are not very sensitive to plausible alternative non-mitigation scenarios for GHG concentrations (specifically the Special Report on Emission Scenarios (SRES) scenarios; comparison with RCP scenarios is discussed in Chapter 1), that is, in the near term, different scenarios give rise to similar magnitudes and patterns of climate change. (Note, however, that some impacts may be more sensitive.) For this reason, most of the projections presented in this chapter are based on one specific RCP scenario, RCP4.5. RCP4.5 was chosen because of its intermediate GHG forcing. However, there is greater sensitivity to other forcing agents, in particular anthropogenic aerosols (e.g., Chalmers et al., 2012). Consequently, a further question addressed in this section (especially in Section 11.3.6.1) is: *To what extent are near-term climate projections sensitive to alternative scenarios for anthropogenic forcing?* Note finally that a great deal of additional information on near-term projections is provided in Annex I.

11.3.1.1 Uncertainty in Near-term Climate Projections

As discussed in Chapters 1 (Section 1.4) and 12 (Section 12.2), climate projections are subject to several sources of uncertainty. Here three main sources are distinguished. The first arises from natural *internal variability*, which is intrinsic to the climate system, and includes phenomena such as variability in the mid-latitude storm tracks and the ENSO. The existence of internal variability places fundamental limits on the precision with which future climate variables can be projected. The second is uncertainty concerning the past, present and future *forcing* of the climate system by natural and anthropogenic forcing agents such as GHGs, aerosols, solar forcing and land use change. Forcing agents may be specified in various ways, for example, as *emissions* or as *concentrations* (see Section 12.2). The third is uncertainty related to the *response* of the climate system to the specified forcing agents.

Quantifying the uncertainty that arises from each of the three sources is an important challenge. For projections, no attempt is made to predict the evolution of the internal variability. Instead, the statistics of this variability are included as a component of the uncertainty associated with a projection. The magnitude of internal variability can be estimated from observations (Chapters 2, 3 and 4) or from climate models (Chapter 9). Challenges arise in estimating the variability on decadal and longer time scales, and for rare events such as extremes, as observational records are often too short to provide robust estimates.

Uncertainty concerning the past forcing of the climate system arises from a lack of direct or proxy observations, and from observational errors. This uncertainty can influence future projections of some variables (particularly large-scale ocean variables) for years or even decades ahead (e.g., Meehl and Hu, 2006; Stenchikov et al., 2009; Gregory, 2010). Uncertainty about future forcing arises from the inability to predict future anthropogenic emissions and land use change, and natural forcings (e.g., volcanoes), and from uncertainties concerning carbon cycle and other biogeochemical feedbacks (Chapters 6, 12 and Annex II.4.1). The uncertainties in future anthropogenic forcing are typically investigated through the development of specific scenarios (e.g., for emissions or concentrations), such as the RCP scenarios (Chapters 1 and 8). Different scenarios give rise to different climate projections, and the spread of such projections is commonly described as *scenario uncertainty.* The sensitivity of climate projections to alternative scenarios for future anthropogenic emissions is discussed especially in Section 11.3.6.1

To project the climate response to specified forcing agents, climate models are required. The term *model uncertainty* describes uncertainty about the extent to which any particular climate model provides an accurate representation of the real climate system. This uncertainty arises from approximations required in the development of models. Such approximations affect the representation of all aspects of the climate including natural internal variability and the response to external forcings. As discussed in Chapter 1 (Section 1.4.2), the term *model uncertainty* is sometimes used in a narrower sense to describe the spread between projections generated using different models or model

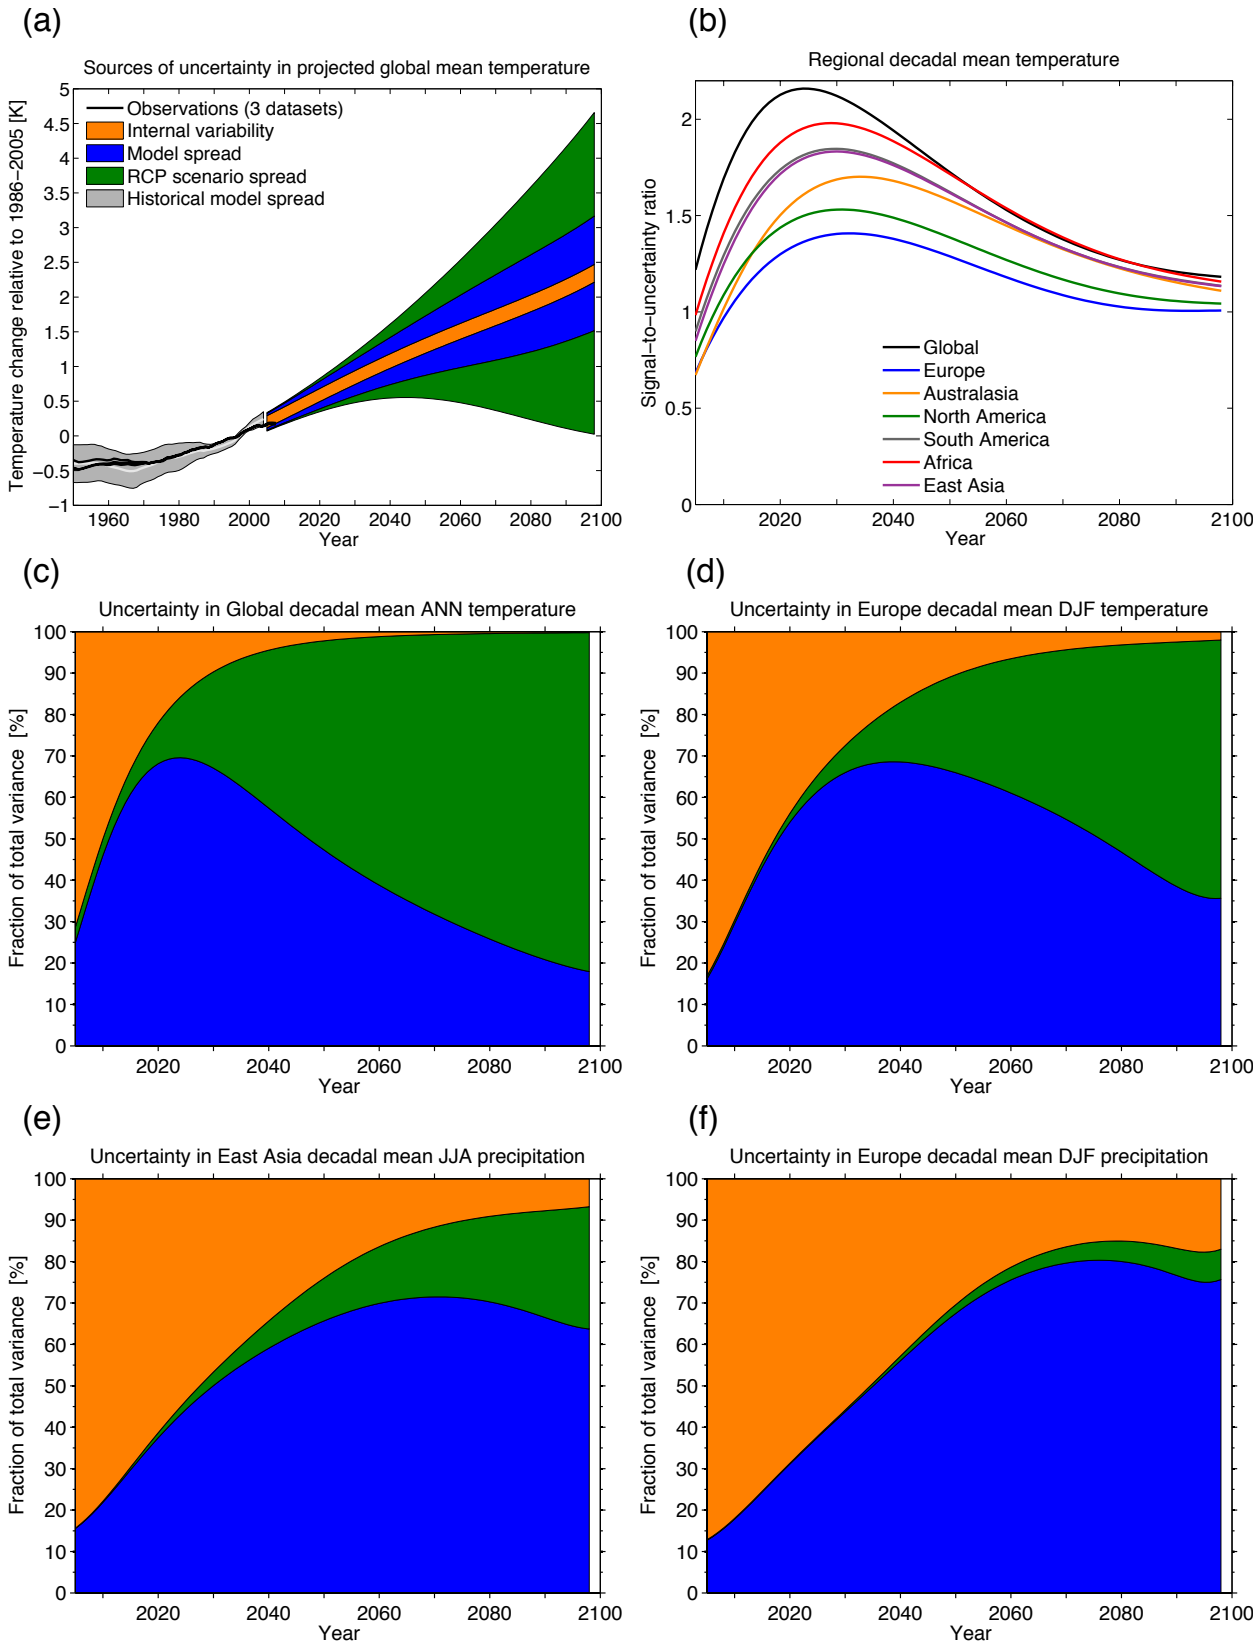

Figure 11.8 | Sources of uncertainty in climate projections as a function of lead time based on an analysis of CMIP5 results. (a) Projections of global mean decadal mean surface air temperature to 2100 together with a quantification of the uncertainty arising from internal variability (orange), model spread (blue) and RCP scenario spread (green). (b) Signal-to-uncertainty ratio for various global and regional averages. The signal is defined as the simulated multi-model mean change in surface air temperature relative to the simulated mean surface air temperature in the period 1986–2005, and the uncertainty is defined as the total uncertainty. (c–f) The fraction of variance explained by each source of uncertainty for: global mean decadal and annual mean temperature (c), European (30°N to 75°N, 10°W to 40°E) decadal mean boreal winter (December to February) temperature (d) and precipitation (f), and East Asian (5°N to 45°N, 67.5°E to 130°E) decadal mean boreal summer (June to August) precipitation (e). See text and Hawkins and Sutton (2009) and Hawkins and Sutton (2011) for further details.

versions; however, such a measure is crude as it takes no account of factors such as model quality (Chapter 9) or model independence. The term *model response uncertainty* is used here to describe the dimension of model uncertainty that is directly related to the response to external forcings. To obtain projections of extreme events such as tropical cyclones, or regional phenomena such as orographic rainfall, it is sometimes necessary to employ a dynamical or statistical downscaling procedure. Such downscaling introduces an additional dimension of model uncertainty (e.g., Alexandru et al., 2007).

The relative importance of the different sources of uncertainty depends on the variable of interest, the space and time scales involved (Section 10.5.4.3 of Meehl et al. (2007b)), and the lead-time of the projection. Figure 11.8 provides an illustration of these dependencies based on an analysis of CMIP5 projections (following Hawkins and Sutton, 2009, 2011;Yip et al., 2011). In this example, the forcing-related uncertainty is estimated using the spread of projections for different RCP scenarios (i.e., scenario uncertainty), while the spread among different models for individual RCP scenarios is used as a measure of the model response uncertainty. Internal variability is estimated from the models as in Hawkins and Sutton (2009). Key points are: (1) the uncertainty in *near-term* projections is dominated by internal variability and model spread. This finding provides some of the rationale for considering near-term projections separately from long-term projections. Note, however, that the RCP scenarios do not sample the full range of uncertainty in future anthropogenic forcing, and that uncertainty in aerosol forcings in particular may be more important than is suggested by Figure 11.8 (see Section 11.3.6.1); (2) internal variability becomes increasingly important on smaller space and time scales; (3) for projections of precipitation, scenario uncertainty is less important and (on regional scales) internal variability is generally more important than for projections of surface air temperature; (4) the full model uncertainty may well be larger or smaller than the model spread due to common errors or unrealistic models.

A key quantity for any climate projection is the signal-to-noise (S/N) ratio (Christensen et al., 2007), where the 'signal' is a measure of the amplitude of the projected climate change, and the noise is a measure of the uncertainty in the projection. Higher S/N ratios indicate more robust projections of change and/or changes that are large relative to background levels of variability. Depending on the purpose, it may be useful to identify the noise with the total uncertainty, or with a specific component such as the internal variability. The evolution of the S/N ratio with lead time depends on whether the signal grows more rapidly than the noise, or vice versa. Figure 11.8 (top right) shows that, when the noise is identified with the total uncertainty, the S/N ratio for surface air temperature is typically higher at lower latitudes and has a maximum at a lead time of a few decades (Cox and Stephenson, 2007; Hawkins and Sutton, 2009). The former feature is primarily a consequence of the greater amplitude of internal variability in mid-latitudes. The latter feature arises because over the first few decades, when scenario uncertainty is small, the signal grows most rapidly, but subsequently, the contribution from scenario uncertainty grows more rapidly than does the signal, so the S/N ratio falls. See Hawkins and Sutton (2009, 2011) for further details.

11.3.2 Near-term Projected Changes in the Atmosphere and Land Surface

11.3.2.1 Surface Temperature

11.3.2.1.1 Global mean surface air temperature

Figure 11.9 (a) and (b) show CMIP5 projections of global mean surface air temperature under RCP4.5. The 5 to 95% range for the projected anomaly for the period 2016–2035, relative to the reference period 1986–2005, is 0.47°C to 1.00°C (see also Table 12.2). However, as discussed in Section 11.3.1.1, this range provides only a very crude measure of uncertainty, and there is no guarantee that the real world must lie within this range. Obtaining better estimates is an important challenge. One approach involves initializing climate models using observations, as discussed in Section 11.2. Figure 11.9 (b) compares multi-model initialized climate predictions (8 models from Smith et al., 2013b), initialized in 2011; 14 CMIP5 decadal prediction experiment models following the methodology of Meehl and Teng (2012), initialized in 2006 with the 'raw' uninitialized CMIP5 projections. The 5 to 95% range for both sets of initialized predictions is cooler (by about 15% for the median values) than the corresponding range for the raw projections, particularly at the upper end. The differences are partly a consequence of initializing the models in a state that is cool (in comparison to the median of the raw projections) as a result of the recent hiatus in global mean surface temperature rise (see Box 9.2). However, it is not yet possible to attribute all of the reasons with confidence because the raw projections are based on a different, and larger, set of models than the initialized predictions, and because of uncertainties related to the bias adjustment of the initialized predictions (Goddard et al., 2013; Meehl et al., 2013d)

Another approach to making projections involves weighting models according to some measure of their quality (see Chapter 9). A specific approach of this type, known as Allen, Stott and Kettleborough (ASK) (Allen et al., 2000; Stott and Kettleborough, 2002), is based on the use of results from detection and attribution studies (Chapter 10), in which the fit between observations and model simulations of the past is used to scale projections of the future. ASK requires specific simulations to be carried out with individual forcings (e.g., anthropogenic GHG forcing alone), and only some of the centres participating in CMIP5 have carried out the necessary integrations. Biases in ASK-derived projections may arise from errors in the specified forcings, or in the simulated patterns of response, and/or from nonlinearities in the responses to forcings.

Figure 11.9c shows the projected range of global mean surface air temperature change derived using the ASK approach for RCP4.5 (Stott and G. Jones, 2012; Stott et al., 2013) applied to six models and compares this with the range derived from the 42 CMIP5 models. In this case decadal means are shown. The 5 to 95% confidence interval for the projected temperature anomaly for the period 2016–2035, based on the ASK method, is 0.39°C to 0.87°C. As for the initialized predictions shown in Figure 11.9b, both the lower and upper values are below the corresponding values obtained from the raw CMIP5 results, although there is substantial overlap between the two ranges. The relative cooling of the ASK results is directly related to evidence presented in

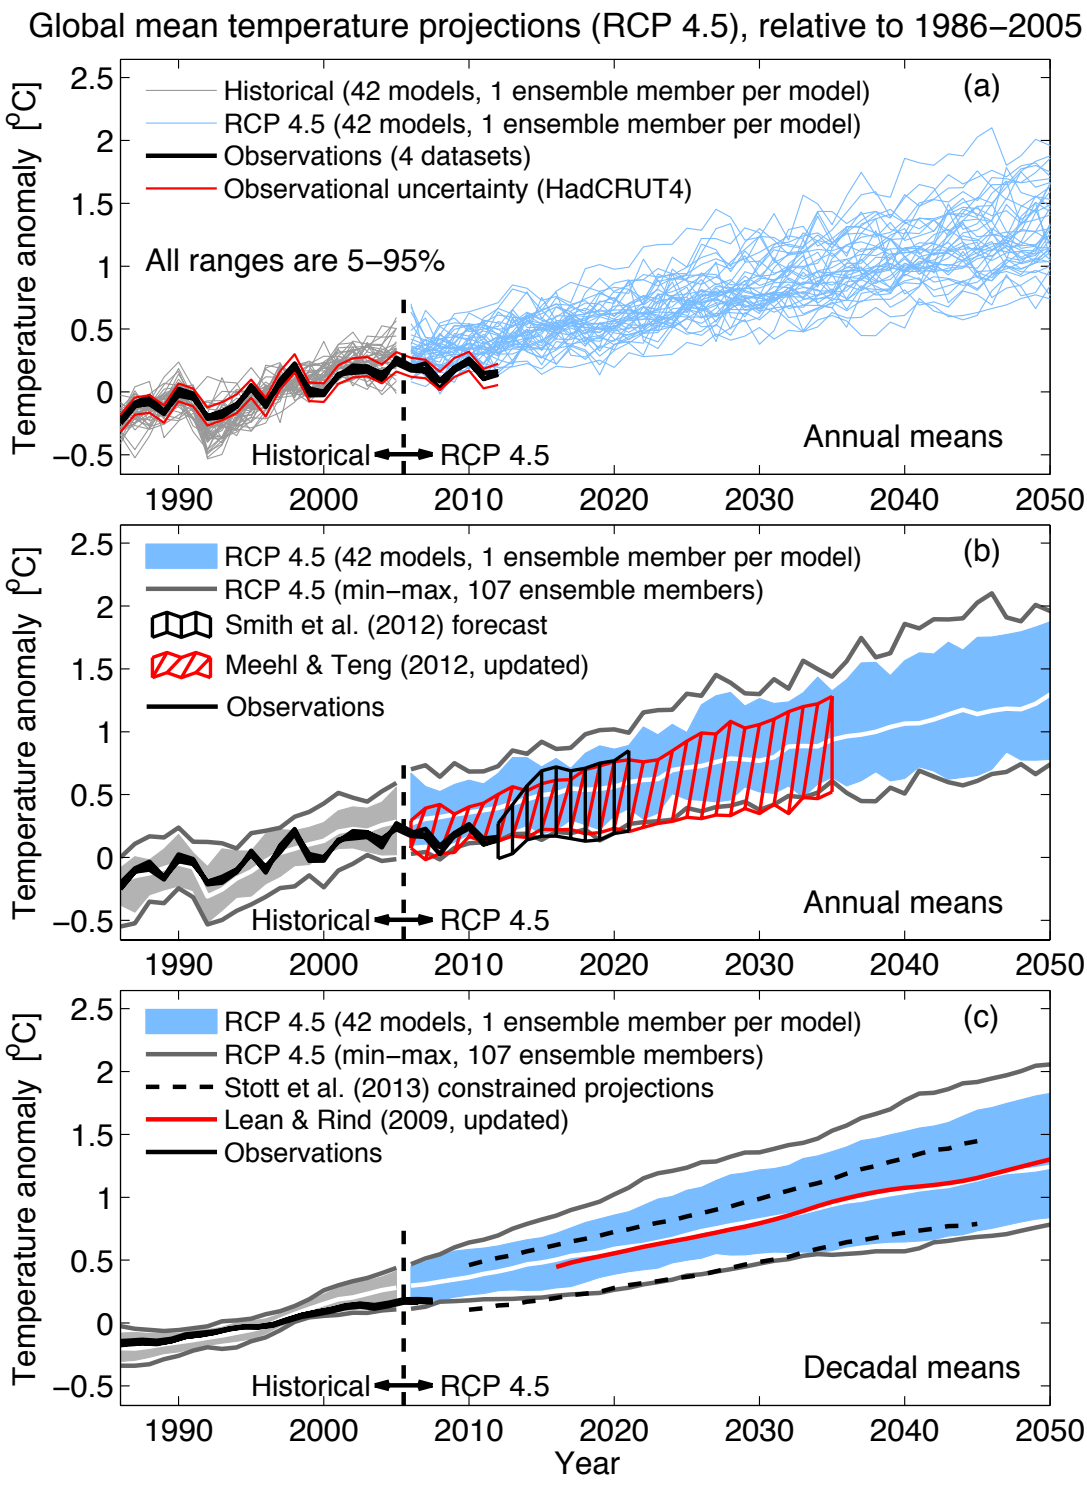

Figure 11.9 | (a) Projections of global mean, annual mean surface air temperature 1986–2050 (anomalies relative to 1986–2005) under RCP4.5 from CMIP5 models (blue lines, one ensemble member per model), with four observational estimates: Hadley Centre/Climate Research Unit gridded surface temperature data set 3 (HadCRUT3: Brohan et al., 2006); European Centre for Medium range Weather Forecast (ECMWF) interim reanalysis of the global atmosphere and surface conditions (ERA-Interim: Simmons et al., 2010); Goddard Institute of Space Studies Surface Temperature Analysis (GISTEMP: Hansen et al., 2010); National Oceanic and Atmospheric Administration (NOAA: Smith et al. (2008) for the period 1986–2011 (black lines). (b) As in (a) but showing the 5 to 95% range (grey and blue shades, with the multi-model median in white) of annual mean CMIP5 projections using one ensemble member per model from RCP4.5 scenario, and annual mean observational estimates (solid black line). The maximum and minimum values from CMIP5 are shown by the grey lines. Red hatching shows 5 to 95% range for predictions initialized in 2006 for 14 CMIP5 models applying the Meehl and Teng (2012) methodology. Black hatching shows the 5 to 95% range for predictions initialized in 2011 for eight models from Smith et al. (2013b). (c) As (a) but showing the 5 to 95% range (grey and blue shades, with the multi-model median in white) of decadal mean CMIP5 projections using one ensemble member per model from RCP4.5 scenario, and decadal mean observational estimates (solid black line). The maximum and minimum values from CMIP5 are shown by the grey lines. The dashed black lines show an estimate of the projected 5 to 95% range for decadal mean global mean surface air temperature for the period 2016–2040 derived using the ASK methodology applied to six CMIP5 GCMs. (From Stott et al., 2013.) The red line shows a statistical prediction based on the method of Lean and Rind (2009), updated for RCP4.5.

Chapter 10 (Section 10.3.1) that 'This provides evidence that some CMIP5 models have a higher transient response to GHGs and a larger response to other anthropogenic forcings (dominated by the effects of aerosols) than the real world (*medium confidence*).' The ASK results and the initialised predictions both suggest that those CMIP5 models that warm most rapidly over the period (1986–2005) to (2016–2035) may be inconsistent with the observations. This possibility is also suggested by comparing the models with the observed rate of warming since 1986—see Box 9.2 for a full discussion of this comparison. Lastly, Figure 11.9 also shows a statistical prediction for global mean surface air temperature, using the method of Lean and Rind (2009), which uses multiple linear regression to decompose observed temperature variations into distinct components. This prediction is very similar to the CMIP5 multi-model median.

The projections shown in Figure 11.9 assume the RCP4.5 scenario and use the 1986–2005 reference period. In Section 11.3.6 additional uncertainties associated with future forcing, climate responses and sensitivity to the choice of reference period, are discussed. An overall assessment of the *likely* range for future global mean surface air temperature is provided in Section 11.3.6.3.

For the remaining projections in this chapter the spread among the CMIP5 models is used as a simple, but crude, measure of uncertainty. The extent of agreement between the CMIP5 projections provides rough guidance about the likelihood of a particular outcome. But—as partly illustrated by the discussion above—it must be kept firmly in mind that the real world could fall outside of the range spanned by these particular models. See Section 11.3.6 for further discussion.

11.3.2.1.2 Regional and seasonal patterns of surface warming

The geographical pattern of near-term surface warming simulated by the CMIP5 models (Figure 11.10) is consistent with previous IPCC reports in a number of key aspects, although weaknesses in the ability of current models to capture observed regional trends (Box 11.2) must be kept in mind. First, temperatures over land increase more rapidly than over sea (e.g., Manabe et al., 1991; Sutton et al., 2007). Processes that contribute to this land–sea warming contrast include different local feedbacks over ocean and land and changes in atmospheric energy transport from ocean to land regions (e.g., Lambert and Chiang, 2007; Vidale et al., 2007; Shimpo and Kanamitsu, 2009; Fasullo, 2010; Boer, 2011; Joshi et al., 2011).

Second, the projected warming in wintertime shows a pronounced polar amplification in the NH (see Box 5.1). This feature is found in virtually all coupled model projections, but the CMIP3 simulations generally appeared to underestimate this effect in comparison to

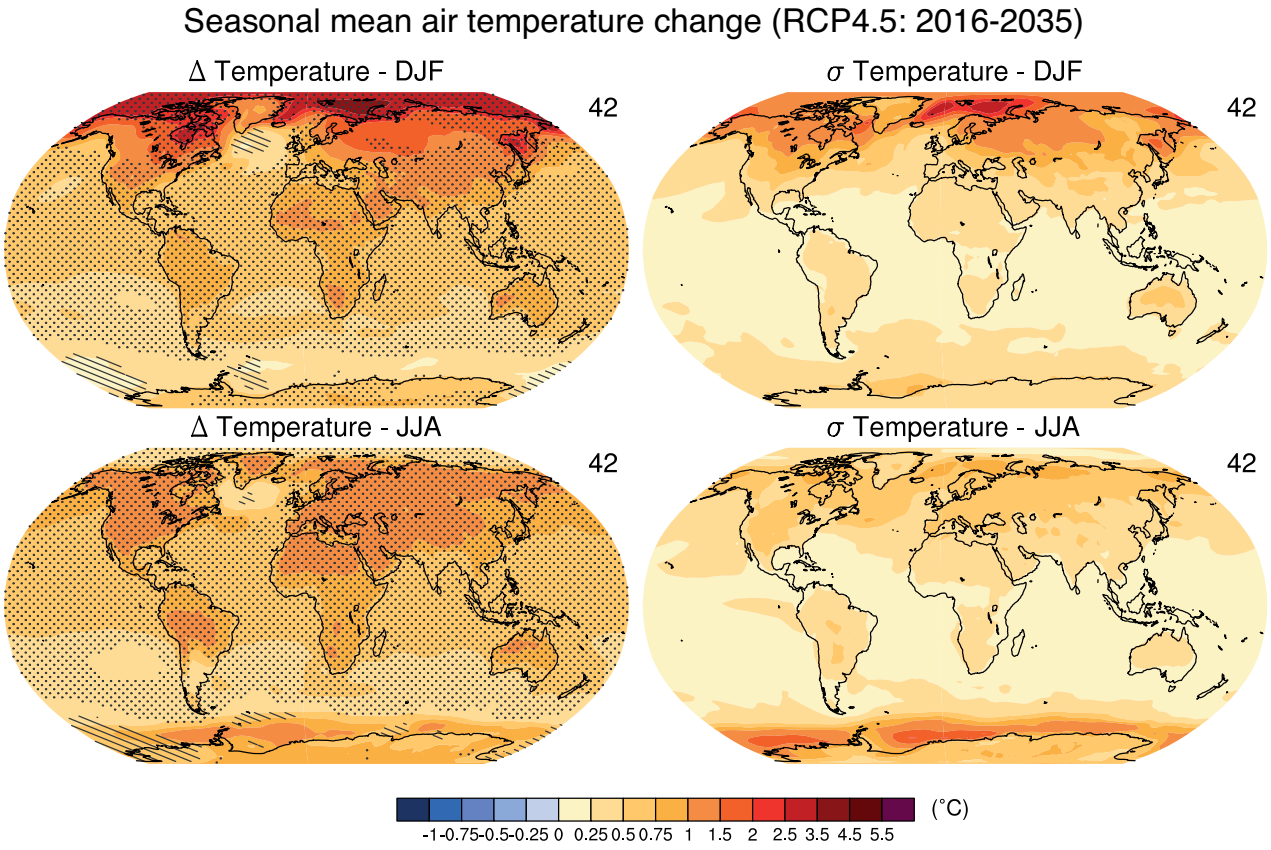

Figure 11.10 | CMIP5 multi-model ensemble mean of projected changes in December, January and February and June, July and August surface air temperature for the period 2016–2035 relative to 1986–2005 under RCP4.5 scenario (left panels). The right panels show an estimate of the model-estimated internal variability (standard deviation of 20-year means). Hatching in left-hand panels indicates areas where projected changes are small compared to the internal variability (i.e., smaller than one standard deviation of estimated internal variability), and stippling indicates regions where the multi-model mean projections deviate significantly from the simulated 1986–2005 period (by at least two standard deviations of internal variability) and where at least 90% of the models agree on the sign of change. The number of models considered in the analysis is listed in the top-right portion of the panels; from each model one ensemble member is used. See Box 12.1 in Chapter 12 for further details and discussion. Technical details are in Annex I.

observations (Stroeve et al., 2007; Screen and Simmonds, 2010). Several studies have isolated mechanisms behind this amplification, which include reductions in snow cover and retreat of sea ice (e.g., Serreze et al., 2007; Comiso et al., 2008); changes in atmospheric and oceanic circulations (Chylek et al., 2009, 2010; Simmonds and Keay, 2009); presence of anthropogenic soot in the Arctic environment (Flanner et al., 2007; Quinn et al., 2008; Jacobson, 2010; Ramana et al., 2010); and increases in cloud cover and water vapour (Francis, 2007; Schweiger et al., 2008). Most studies argue that changes in sea ice are central to the polar amplification—see Section 11.3.4.1 for further discussion. Further information about the regional changes in surface air temperature projected by the CMIP5 models is presented in Annex I.

As discussed in Sections 11.1 and 11.3.1, the signal of climate change is emerging against a background of natural internal variability. The concept of 'emergence' describes the magnitude of the climate change signal relative to this background variability, and may be useful for some climate impact assessments (e.g., AR4, Chapter 11, Table 11.1; Mahlstein et al., 2011; Hawkins and Sutton, 2012; see also FAQ 10.2). However, it is important to recognize that there is no single metric of emergence. It depends on user-driven choices of variable, space and time scale, of the baseline relative to which changes are measured (e.g., pre-industrial versus recent climate) and of the threshold at which emergence is defined.

Figure 11.11 quantifies the 'Time of Emergence' (ToE) of the mean warming signal relative to the recent past (1986–2005), based on the CMIP5 RCP4.5 projections, using a spatial resolution of 2.5° latitude × 2.5° longitude, the standard deviation of interannual variations as the measure of internal variability, and a signal-to-noise threshold of 1. Because of the dependence on user-driven choices, the most important information in Figure 11.11 is the geographical and seasonal variation in ToE, seen in the maps, and the variation in ToE between models, shown in the histograms. Consistent with Mahlstein et al. (2011), the earliest ToE is found in the tropics, with ToE in mid-latitudes typically a decade or so later. Over North Africa and Asia, earlier ToE is found for the warm half-year (April to September) than for the cool half-year. Earlier ToE is generally found for larger space and time scales, because the variance of natural internal variability decreases with averaging (Section 11.3.1.1 and AR4, Section 10.5.4.3). This tendency can be seen in Figure 11.11 by comparing the median value of the histograms for area averages with the area average of the median ToE inferred from the maps (e.g., for Region 2). The large range of values for ToE implied by different CMIP5 models, which can be as much as 30 years, is a consequence of differences in both the magnitude of the warming signal simulated by the models (i.e., uncertainty in the climate response, see Section 11.3.1.1) and in the amplitude of simulated natural internal variability (Hawkins and Sutton, 2012).

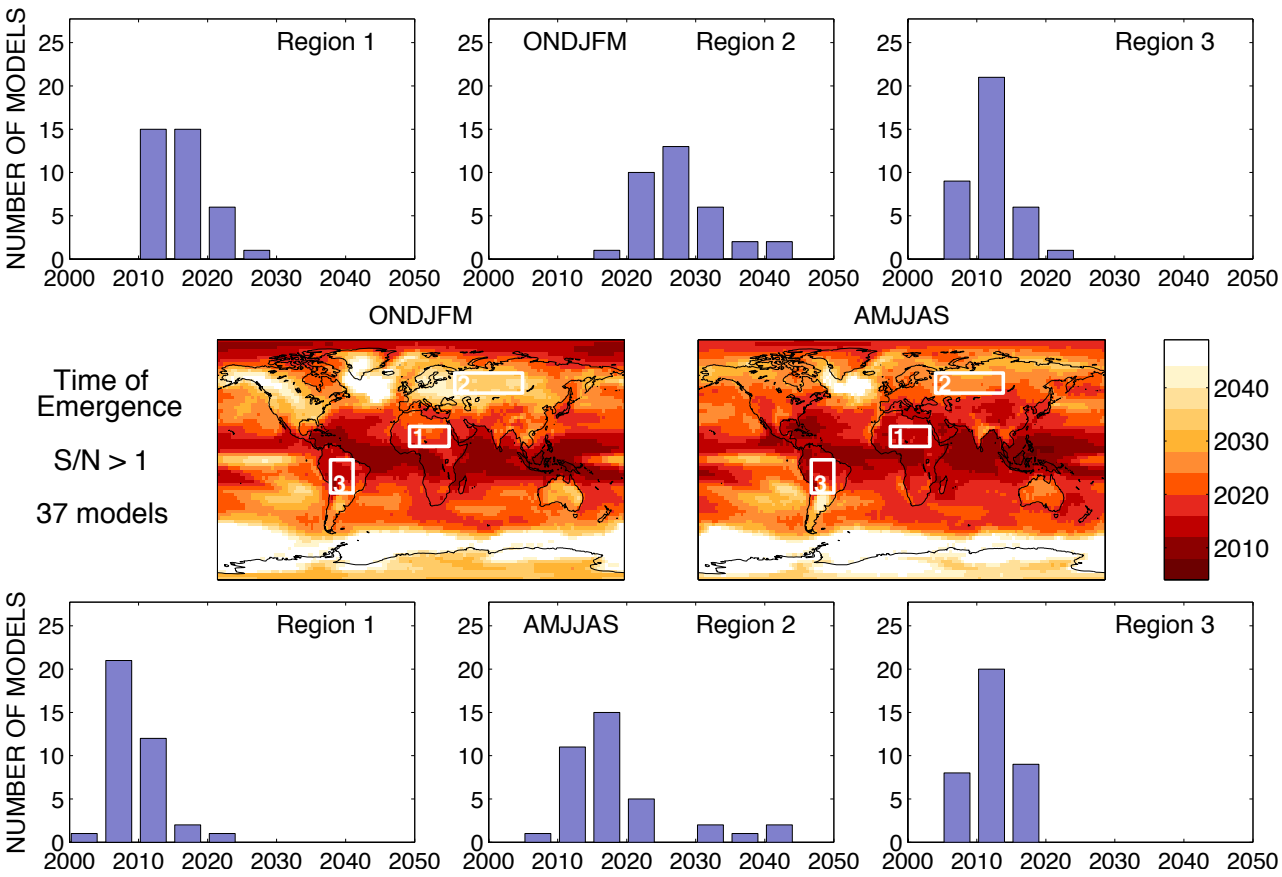

Figure 11.11 | Time of Emergence (ToE) of significant local warming derived from 37 CMIP5 models under the RCP4.5 scenario. Warming is quantified as the half-year mean temperature anomaly relative to 1986–2005, and the noise as the standard deviation of half-year mean temperature derived from a control simulation of the relevant model. Central panels show the median time at which the signal-to-noise ratio exceeds a threshold value of 1 for (left) the October to March half year and (right) the April to September half year, using a spatial resolution of 2.5° × 2.5°. Histograms show the distribution of ToE for area averages over the regions indicated obtained from the different CMIP5 models. Full details of the methodology may be found in Hawkins and Sutton (2012).

In summary, it is *very likely* that anthropogenic warming of surface air temperature over the next few decades will proceed more rapidly over land areas than over oceans, and that the warming over the Arctic in winter will be greater than the global mean warming over the same period. Relative to background levels of natural internal variability, near-term increases in seasonal mean and annual mean temperatures are expected to occur more rapidly in the tropics and subtropics than in mid-latitudes (*high confidence*).

11.3.2.2 Free Atmospheric Temperature

Changes in zonal mean temperature for the near-term period (2016–2035 compared to the base period 1986–2005) for the multi-model CMIP5 ensemble show a pattern similar to that in the CMIP3, with warming in the troposphere and cooling in the stratosphere of a couple of degrees that is significant even in the near term period. There is relatively greater warming in the tropical upper troposphere and northern high latitudes. A more detailed assessment of observed and simulated changes in free atmospheric temperatures can be found in Sections 10.3.1.2.1 and 12.4.3.2.

11.3.2.3 The Water Cycle

As discussed in the AR4 (Section 10.3.6; Meehl et al., 2007b), the IPCC Technical Paper on Climate Change and Water (Bates et al., 2008) and the Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (Seneviratne et al., 2012), a general intensification of the global hydrological cycle, and of precipitation extremes, are expected for a future warmer climate (e.g., (Huntington, 2006; Williams et al., 2007; Wild et al., 2008; Chou et al., 2009; Dery et al., 2009; O'Gorman and Schneider, 2009; Lu and Fu, 2010; Seager et al., 2010; Wu et al., 2010; Kao and Ganguly, 2011; Muller et al., 2011; Durack et al., 2012). In this section, projected changes in the time-mean hydrological cycle are discussed; changes in extremes, are presented in Section 11.3.2.5 while processes underlying precipitation changes are treated in Chapter 7.

11.3.2.3.1 Changes in precipitation

AR4 projections of the spatial patterns of precipitation change in response to GHG forcing (Chapter 10, Section 10.3.2) showed consistency between models on the largest scales (i.e., zonal means) but large uncertainty on smaller scales. The consistent pattern was characterized by increases at high latitudes and in wet regions (including the maxima in mean precipitation found in the tropics), and decreases in dry regions (including large parts of the subtropics). Large uncertainties in the sign of projected change were seen especially in regions located on the borders between regions of increases and regions of decreases. More recent research has highlighted the fact that if models agree that the projected change is small in some sense relative to internal variability, then agreement on the sign of the change is not expected (Tebaldi et al., 2011; Power et al., 2012). This recognition led to the identification of subregions within the border regions, where models agree that projected changes are either zero or small (Power et al., 2012). This, and other considerations, also led to the realization that the consensus among models on precipitation projections is more widespread than might have been inferred on the basis of the projections described in the AR4 (Power et al., 2012). Information on the reliability of near-term projections can also be obtained from verification of past regional trends (Räisänen (2007); Box 11.2)

Since the AR4 there has also been considerable progress in understanding the factors that govern the spatial pattern of change in precipitation (P), precipitation minus evaporation ($P - E$), and inter-model differences in these patterns. The general pattern of wet-get-wetter (also referred to as 'rich-get-richer', e.g., Held and Soden, 2006; Chou et al., 2009; Allan et al., 2010) and dry-get-drier has been confirmed, although with deviations in some dry regions at present that are projected to become wetter by some models, e.g., Northeast Brazil in austral summer and East Africa (see Annex I). It has been demonstrated that the wet-get-wetter pattern implies an enhanced seasonal precipitation range between wet and dry seasons in the tropics, and enhanced inter-hemispheric precipitation gradients (Chou et al., 2007).

It has recently been proposed that analysis of the energy budget, previously applied only to the global mean, may provide further insights into the controls on regional changes in precipitation (Levermann et al., 2009; Muller and O'Gorman, 2011; O'Gorman et al., 2012). Muller and O'Gorman (2011) argue in particular that changes in radiative and surface sensible heat fluxes provide a guide to the local precipitation response over land. Projected and observed patterns of oceanic precipitation change in the tropics tend to follow patterns of SST change because of local changes in atmospheric stability, such that regions warming more than the tropics as a whole tend to exhibit an increase in local precipitation, while regions warming less tend to exhibit reduced precipitation (Johnson and Xie, 2010; Xie et al., 2010).

AR4 (Section 10.3.2 and Chapter 11) showed that, especially in the near term, and on regional or smaller scales, the magnitude of projected changes in mean precipitation was small compared to the magnitude of natural internal variability (Christensen et al., 2007). Recent work has confirmed this result, and provided more quantification (e.g., Hawkins and Sutton, 2011; Hoerling et al., 2011; Rowell, 2011; Deser et al., 2012; Power et al., 2012). Hawkins and Sutton (2011) presented further analysis of CMIP3 results and found that, on spatial scales of the order of 1000 km, internal variability contributes 50 to 90% of the total uncertainty in all regions for projections of decadal and seasonal mean precipitation change for the next decade, and is the most important source of uncertainty for many regions for lead times up to three decades ahead (Figure 11.8). Thereafter, response uncertainty is generally dominant. Forcing uncertainty (except for that relating to aerosols, see Section 11.4.7) is generally negligible for near-term projections. The S/N ratio for projected changes in seasonal mean precipitation is highest in the subtropics and at high latitudes. Rowell (2011) found that the contribution of response uncertainty to the total uncertainty (response plus internal variability) in local precipitation change is highest in the deep tropics, particularly over South America, Africa, the east and central Pacific, and the Atlantic. Over tropical land and summer mid-latitude continents the representation of SST changes, atmospheric processes, land surface processes, and the terrestrial carbon cycle all contribute to the uncertainty in projected changes in rainfall.

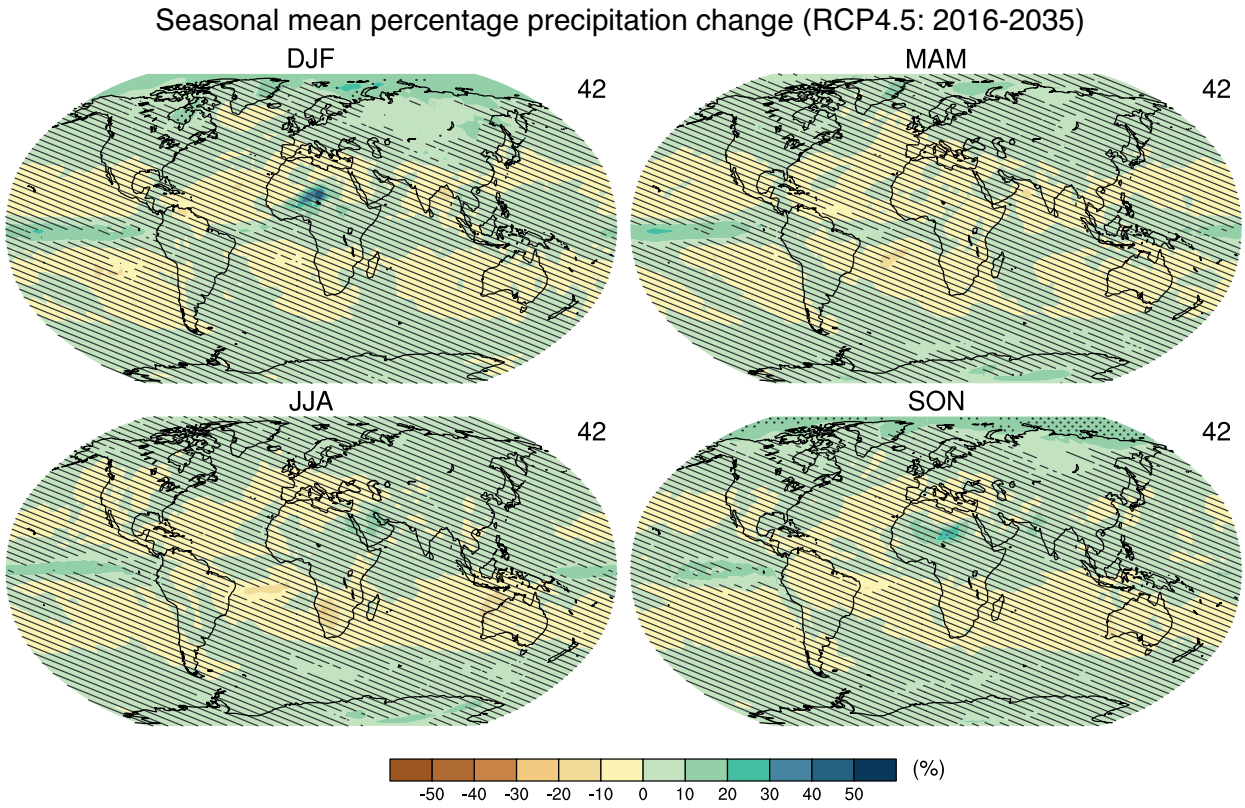

Figure 11.12 | CMIP5 multi-model ensemble mean of projected changes (%) in precipitation for 2016–2035 relative to 1986–2005 under RCP4.5 for the four seasons. The number of CMIP5 models used is indicated in the upper right corner. Hatching and stippling as in Figure 11.10.

In addition to the response to GHG forcing, forcing from natural and anthropogenic aerosols may exert significant impacts on regional patterns of precipitation change as well as on global mean temperature (Bollasina et al., 2011; Yue et al., 2011; Fyfe et al., 2012). Precipitation changes may arise as a consequence of temperature and stratification changes driven by aerosol-induced radiative effects, and/or as indirect aerosol effects on cloud microphysics (Chapter 7). Future emissions of aerosols and aerosol precursors are subject to large uncertainty, and further large uncertainties arise in assessing the responses to these emissions. These issues are discussed in Section 11.3.6.

Figures 11.12 and 11.13a present projections of near-term changes in precipitation from CMIP5. Regional maps and time series are presented in Annex I. The basic pattern of wet regions tending to get wetter and dry regions tending to get dryer is apparent, although with some regional deviations as mentioned previously. However, the

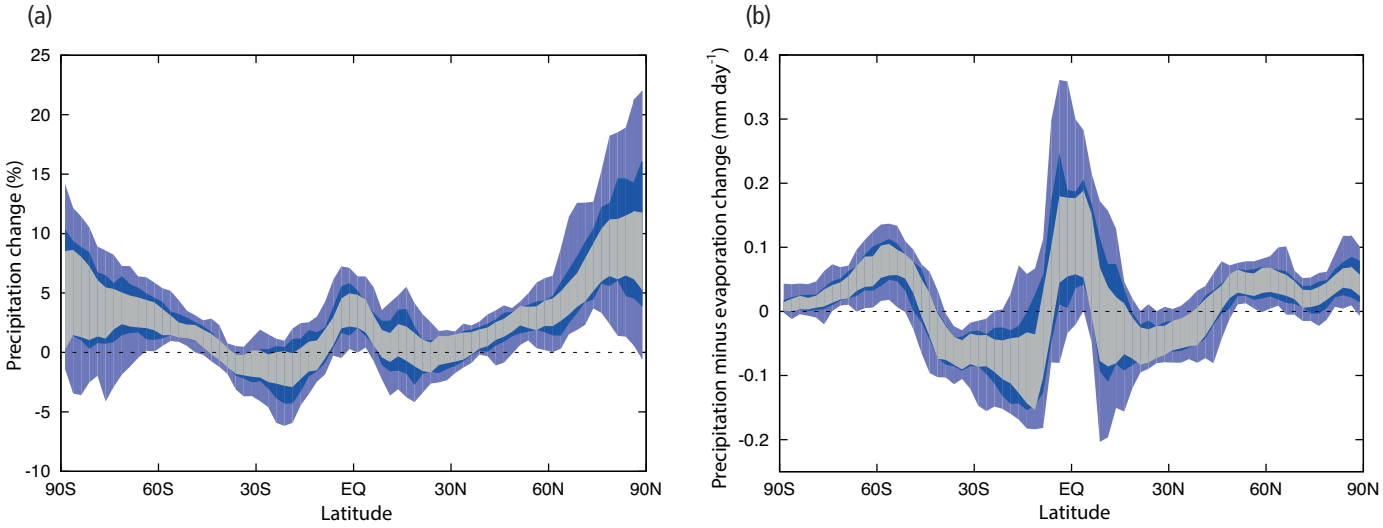

Figure 11.13 | CMIP5 multi-model projections of changes in annual and zonal mean (a) precipitation (%) and (b) precipitation minus evaporation (mm day^{-1}) for the period 2016–2035 relative to 1986–2005 under RCP4.5. The light blue denotes the 5 to 95% range, the dark blue the 17 to 83% range of model spread. The grey indicates the 1σ range of natural variability derived from the pre-industrial control runs (see Annex I for details).

large response uncertainty is evident in the substantial spread in the magnitude of projected change simulated by different climate models (Figure 11.13a). In addition, it is important to recognize—as discussed in previous sections—that models may agree and still be in error (e.g., Power et al. 2012). In particular, there is some evidence from comparing observations with simulations of the recent past that climate models might be underestimating the magnitude of changes in precipitation in many regions (Pincus et al., 2008; Liepert and Previdi, 2009; Schaller et al., 2011; Joetzjer et al., 2012) This evidence is discussed in detail in Chapter 9 (Section 9.4.1) and Box 11.2, and could imply that projected changes in precipitation are underestimated by current models. However, the magnitude of any underestimation has yet to be quantified, and is subject to considerable uncertainty.

Figures 11.12 and 11.13a also highlight the large amplitude of the natural internal variability of mean precipitation. On regional scales, mean projected changes are almost everywhere smaller than the estimated standard deviation of natural internal variability. The only exceptions are the northern high latitudes and the equatorial Pacific Ocean (Figure 11.12). For zonal means (Figure 11.13a) and at high latitudes only, the projected changes relative to the recent past exceed the estimated standard deviation of internal variability.

Overall, zonal mean precipitation will *very likely* increase in high and some of the mid latitudes, and will *more likely than not* decrease in the subtropics. At more regional scales precipitation changes may be influenced by anthropogenic aerosol emissions and will be strongly influenced by natural internal variability.

11.3.2.3.2 Changes in evaporation, evaporation minus precipitation, runoff, soil moisture, relative humidity and specific humidity

Because the variability of the atmospheric moisture storage is negligible, global mean increases in evaporation are required to balance increases in precipitation in response to anthropogenic forcing (Meehl et al., 2007a; Trenberth et al., 2007; Bates et al., 2008; Lu and M. Cai, 2009). The global atmospheric water content is constrained by the Clausius–Clapeyron equation to increase at around 7% K^{-1}; however, both the global precipitation and evaporation in global warming simulations increase at 1 to 3% K^{-1} (Lambert and Webb, 2008; Lu and M.Cai, 2009).

Changes in evapotranspiration over land are influenced not only by the response to RF, but also by the vegetation response to elevated CO_2 concentrations. Physiological effects of CO_2 may involve both the stomatal response, which acts to restrict transpiration (Field et al., 1995; Hungate et al., 2002; Cao et al., 2009, 2010; Lammertsma et al., 2011), and an increase in plant growth and leaf area, which acts to increase evapotranspiration (El Nadi, 1974; Bounoua et al., 2010). Simulation of the latter process requires the inclusion of vegetation models that allow spatial and temporal variability in the amount of active biomass, either by changes in the phenological cycle or changes in the biome structure.

In response to GHG forcing, dry land areas tend to show a reduction of evaporation and often precipitation, accompanied by a drying of the soil and an increase of surface temperature, in response to decreases in latent heat fluxes from the surface (e.g., Fischer et al., 2007; Seneviratne et al., 2010). Jung et al. (2010) use a mixture of observations and models to illustrate a recent global mean decline in land surface evaporation due to soil-moisture limitations. Accompanying precipitation effects are more subtle, as there are significant uncertainties and large geographical variations regarding the soil-moisture precipitation feedback (Hohenegger et al., 2009; Taylor et al., 2011). AR4 projections (Meehl et al. (2007b) of annual mean soil moisture changes for the 21st century showed a tendency for decreases in the subtropics, southern South America and the Mediterranean region, and increases in limited areas of east Africa and central Asia. Changes seen in other regions were mostly not consistent or statistically significant.

AR4 projections of 21st century runoff changes (Meehl et al., 2007b) showed consistency in sign among models indicating annual mean reductions in southern Europe and increases in Southeast Asia and at high northern latitudes. Projected changes in global mean runoff associated with the physiological effects of doubled CO_2 concentrations show increases of 6 to 8% relative to pre-industrial levels, an increase that is comparable to that simulated in response to RF changes (11% ± 6%) (Betts et al., 2007; Cao et al., 2010). Gosling et al. (2011) assess the projected impacts of climate change on river runoff from global and basin-scale hydrological models obtaining increased runoff with global warming in the Liard (Canada), Rio Grande (Brazil) and Xiangxi (China) basins and decrease for the Okavango (southwest Africa).

Consideration of hydrological drought conditions employs a range of different dryness indicators, such as soil moisture or other drought indices that integrate precipitation and evaporation effects (Seneviratne et al., 2012). There are large uncertainties in regional drought projections (Burke and Brown, 2008), and very few studies have addressed the near-term future (Sheffield and Wood, 2008; Dai, 2011). In order to provide an indication of future changes of water availability, Figure 11.13b presents zonal mean changes in precipitation minus evaporation ($P - E$) from CMIP5. As in the case of precipitation (Figure 11.13a), the uncertainty is dominated by model differences as opposed to natural variability (compare blue versus grey shading). The results are consistent with the wet-get-wetter and dry-get-drier pattern (e.g., Held and Soden 2006): In the high latitudes and the tropics, most of the models project zonal-mean increases in $P - E$, which over land would need to be compensated by increases in runoff (see next paragraph). In contrast, zonal mean projected changes in the subtropics are negative, indicating decreases in water availability. Although this pattern is evident in most or all of the models, and although several studies project drought increases in the near term future (Sheffield and Wood, 2008; Dai, 2011), the assessment is debated in the literature based on discrepancies in the recent past and due to natural variability (Seneviratne et al., 2012; Sheffield et al., 2012).

The global distribution of the 2016–2035 changes in annual mean evaporation, evaporation minus precipitation ($E - P$), surface runoff, soil moisture, relative humidity and surface-level specific humidity from the CMIP5 multi-model ensemble under RCP4.5 are shown in Figure 11.14. Changes in evaporation over land (Figure11.14a), are mostly positive with the largest values at northern high latitudes, in agreement with projected temperature increases (Figure 11.10). Over the oceans, evaporation is also projected to increase in most regions. Projected changes

are larger than the estimated standard deviation of internal variability only at high latitudes and over the tropical oceans. Decreases in evaporation over land (i.e., Australia, southern Africa, northeastern South America and Mexico) and oceans are smaller than the estimated standard deviation of internal variability; the only exception is the western North Atlantic, although the model agreement is low in that region. Projected changes in ($E - P$) over land (Figure 11.14b) are generally consistent with the zonal mean changes shown in Figure 11.13b. In the high northern latitudes and the tropics, ($E - P$) changes are mostly negative as dominated by precipitation increases (Figure 11.12), while in

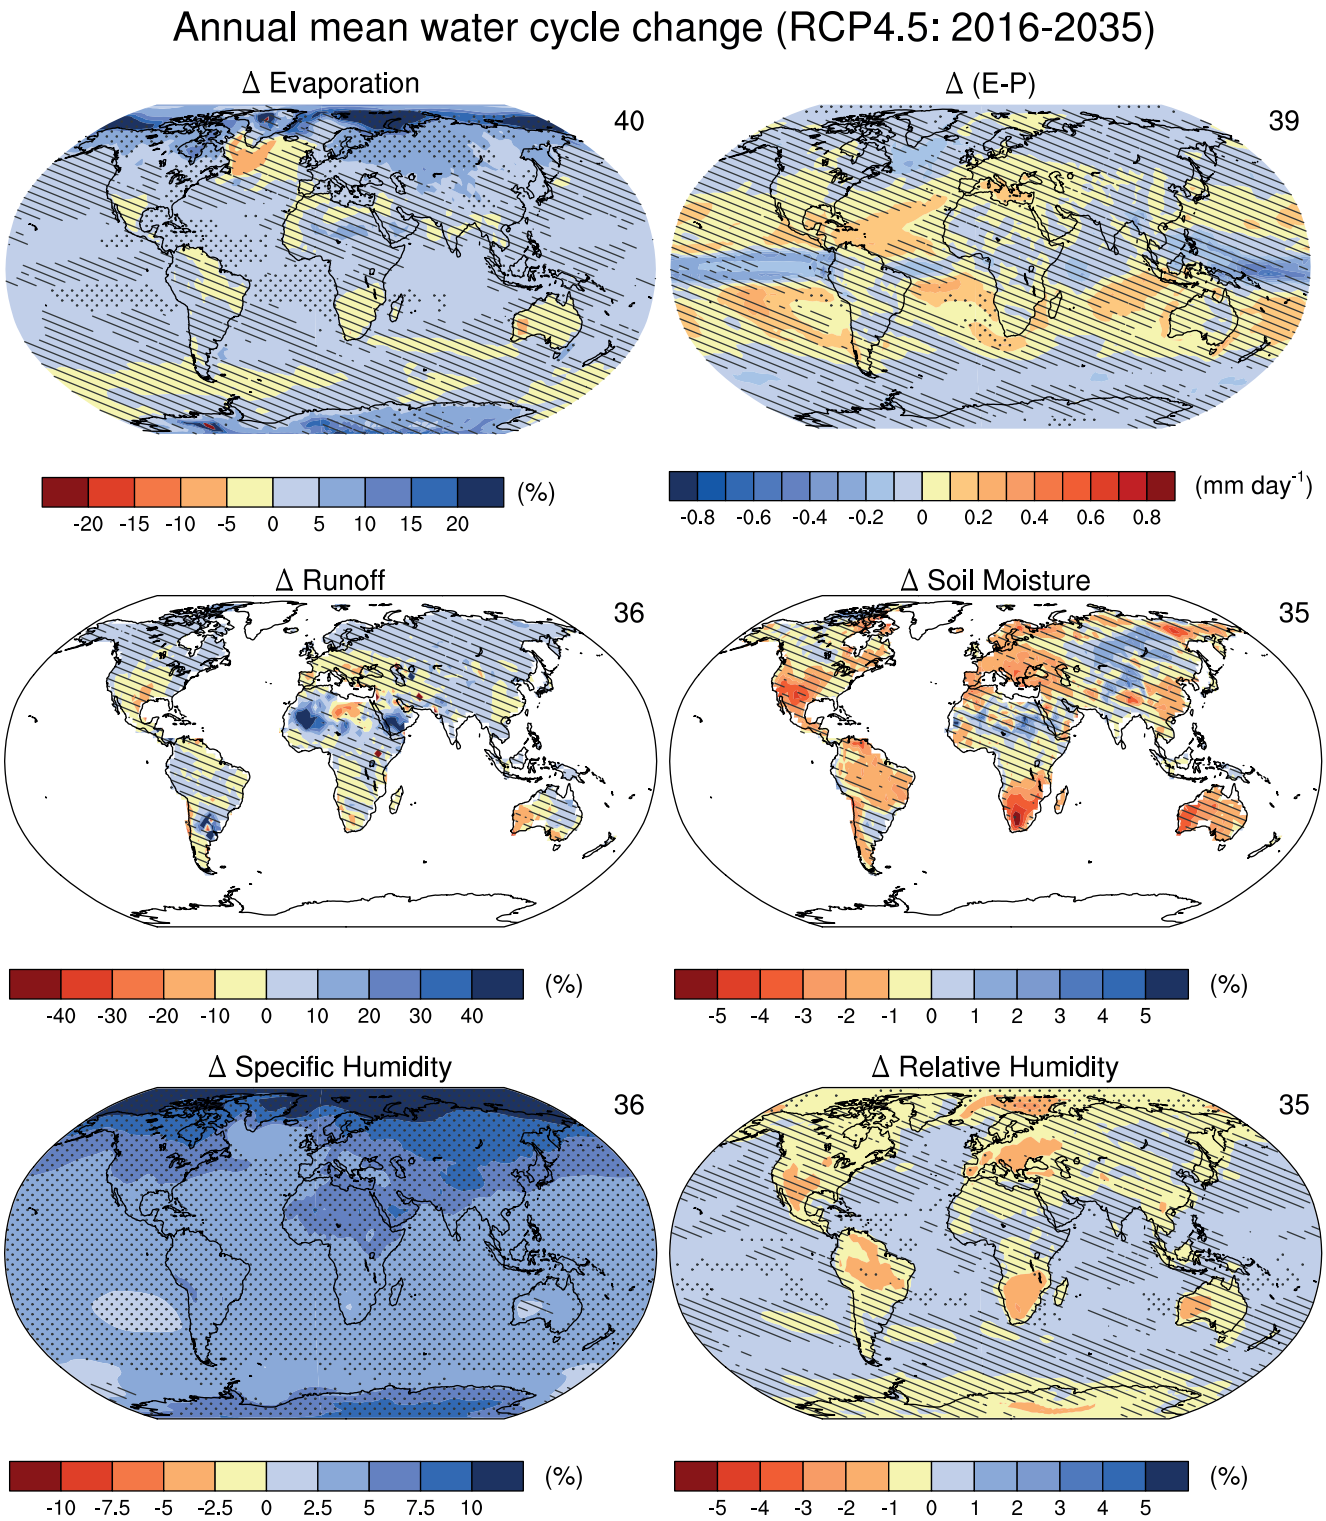

Figure 11.14 | CMIP5 multi-model annual mean projected changes for the period 2016–2035 relative to 1986–2005 under RCP4.5 for: (a) evaporation (%), (b) evaporation minus precipitation ($E - P$, mm day^{-1}), (c) total runoff (%), (d) soil moisture in the top 10 cm (%), (e) relative change in specific humidity (%), and (f) absolute change in relative humidity (%). The number of CMIP5 models used is indicated in the upper right corner of each panel. Hatching and stippling as in Figure 11.10.

the subtropics several areas exhibit increases in ($E - P$), in particular in Europe, western Australia and central-western USA. However, in most locations changes are smaller than internal variability.

Annual mean shallow soil moisture (Figure 11.14d) shows decreases in most subtropical regions (except La Plata basin in South America) and in central Europe, and increases in northern mid-to-high latitudes. Projected changes are larger than the estimated internal variability only in southern Africa, the Amazon region and Europe. Projected changes in runoff (Figure 11.14c) show decreases in northern Africa, western Australia, southern Europe and southwestern USA and increases larger than the internal variability in northwestern Africa, southern Arabia and southeastern South America associated to the projected changes in precipitation (Figure 11.12). Owing to the simplified hydrological models in many CMIP5 climate models, the projections of soil moisture and runoff have large model uncertainties.

Changes in near-surface specific humidity are positive, with the largest values at northern high latitudes when expressed in percentage terms (Figure 11.14e). This is consistent with the projected increases in temperature when assuming constant relative humidity. These changes are larger than the estimated standard deviation of internal variability almost everywhere: the only exceptions are oceanic regions such as the northern North Atlantic and around Antarctica. In comparison, absolute changes in near-surface relative humidity (Figure 11.14f) are much smaller, on the order of a few percent, with general decreases over most land areas, and small increases over the oceans. Significant decreases relative to natural variability are projected in the Amazonia, southern Africa and Europe, although the model agreement in these regions is low.

Over the next few decades projected increases in near-surface specific humidity are *very likely*, and projected increases in evaporation are *likely* in many land regions. There is *low confidence* in projected changes in soil moisture and surface runoff.

11.3.2.4 Atmospheric Circulation

11.3.2.4.1 Northern Hemisphere extratropical circulation

In the NH extratropics, some Atmosphere–Ocean General Circulation Models (AOGCMs) indicate changes to atmospheric circulation from anthropogenic forcing by the mid-21st century, including a poleward shift of the jet streams and associated zonal mean storm tracks (Miller et al., 2006; Pinto et al., 2007; Paeth and Pollinger, 2010) and a strengthening of the Atlantic storm track (Pinto et al., 2007), Figure 11.15. Consistent with this, the CMIP5 AOGCMs exhibit an ensemble mean increase in the North Atlantic Oscillation (NAO) and Northern Annular Model (NAM) indices by 2050, especially in autumn and winter (Gillett et al., 2013).

However, there are reasons to be cautious over these near-term projections. Although models simulate the broad features of the large-scale circulation well, there remain quite significant biases in many models (see Sections 9.4.1.4.3 and 9.5.3.2). The response of the NH circulation can be sensitive to small changes in model formulation (Sigmond et al., 2007), and to features that are known to be poorly simulated in many climate models. These features include high- and low-latitude physics (Rind, 2008; Woollings, 2010), ocean circulation (Woollings and Blackburn, 2012), tropical circulation (Haarsma and Selten, 2012) and stratospheric dynamics (Huebener et al., 2007; Morgenstern et al., 2010; Scaife et al., 2012). As a result, there is considerable model uncertainty in the response of the NH storm track position (Ulbrich et al., 2008), stationary waves (Brandefelt and Kornich, 2008) and the jet streams (Miller et al., 2006; Ihara and Kushnir, 2009; Woollings and Blackburn, 2012). Further, CMIP5 models show that the response of NH extratropical circulation to even strong GHG forcing remains weak compared to recent multidecadal variability and a recent detection and attribution study suggests that tropospheric ozone and aerosol changes may have been a key driver to NH extratropical circulation changes (Gillett et al., 2013). Some AOGCMs simulate multi-decadal NAO variability as large as that recently observed with no external forcing (Selten et al., 2004; Semenov et al., 2008). This suggests that internal variability could dominate the anthropogenically forced response in the near term (Deser et al., 2012).

Some studies have predicted a shift to the negative phase of the Atlantic Multi-decadal Oscillation (AMO) over the coming few decades, with potential impacts on atmospheric circulation around the Atlantic sector (Knight et al., 2005; Sutton and Hodson, 2005; Folland et al., 2009). It has also been suggested that there may be significant changes in solar forcing over the next few decades, which could have an influence on NAO-related atmospheric circulation (Lockwood et al., 2011), although these predictions are highly uncertain (see Section 11.3.6.2.2).

There is only *medium confidence* in near-term projections of a northward shift of NH storm track and westerlies, and an increase of the NAO/NAM because of the large response uncertainty and the potentially large influence of internal variability.

11.3.2.4.2 Southern Hemisphere extratropical circulation

Increases in GHGs, and related dynamical processes, are projected to lead to poleward shifts in the annual mean position of Southern Hemisphere (SH) extratropical storm tracks and winds (Figure 11.17; Chapters 10 and 12). A key issue in projections of near-term SH extratropical circulation change is the extent to which changes driven by stratospheric ozone recovery will counteract changes driven by increasing GHGs. Several observational and modeling studies (Gillett and Thompson, 2003; Shindell and Schmidt, 2004; Arblaster and Meehl, 2006; Roscoe and Haigh, 2007; Fogt et al., 2009; Polvani et al., 2011a; Gillett et al., 2013) indicate that, over the late 20th and early 21st centuries, the observed summertime poleward shift of the westerly jet (a positive Southern Annular Mode (SAM)) has been caused primarily by the depletion of stratospheric ozone, with increasing GHGs contributing only a smaller fraction to the observed trends. The latest generation of climate models project substantially smaller poleward trends in SH atmospheric circulation in austral summer over the coming half century compared to those over the late 20th century, as the recovery of stratospheric ozone will oppose the effects of continually increasing GHGs (Arblaster et al., 2011; McLandress et al., 2011; Polvani et al., 2011a; Eyring et al., 2013). Locally, internal variability may be a dominant contributor to near-term changes in lower-tropospheric zonal winds (Figure 11.17). The average 2016–2035 SH extratropical storm tracks and zonal

winds are *likely* to shift poleward relative to 1986–2005. However, even though a full recovery of the ozone hole is not expected until the 2060s to 2070s (Table 5.4; WMO, 2010; see Chapter 12), it is *likely* that over the near term there will be a reduced rate in the austral summertime poleward shift of the SH circumpolar trough, SH extratropical storm tracks and winds compared to its movement over the past 30 years, including the possibility of no detectable shift.

11.3.2.4.3 Tropical circulation

Increases in GHGs are expected to lead to a poleward shift of the Hadley Circulation (Lu et al., 2007; Chapter 12, Figure 11.18). Relative to the late 20th century, the tendency towards a poleward expansion of the Hadley Circulation will start to emerge by the mid-2030s, with certain intra-model consensus in the SH expansion, despite the counteracting effect of ozone recovery (Figure 11.18). As with near-term changes in SH extratropical circulation, a key for near-term projections of the structure of the SH Hadley Circulation is the extent to which future stratospheric ozone recovery will counteract the impact of GHGs. The poleward expansion of the Hadley Circulation, particularly of the SH branch during austral summer, during the later decades of the 20th century has been largely attributed to the combined impact of stratospheric ozone depletion (Thompson and Solomon, 2002; Son et al., 2008, 2009a, 2009b; Polvani et al., 2011a, 2011b; Min and Son, 2013) and the concurrent increase in GHGs (Arblaster and Meehl, 2006; Arblaster et al., 2011) as discussed in the previous section. The poleward expansion of the Hadley Circulation driven by the response of the atmosphere to increasing GHGs (Lu et al., 2007; Kang et al., 2011; Staten et al., 2011; Butler et al., 2012) would be counteracted in the SH by reduced stratospheric ozone depletion but depends on the rate of ozone recovery (UNEP and WMO, 2011). Increases in the incoming solar radiation can lead to a widening of the Hadley Cell (Haigh, 1996; Haigh et al., 2005) and large volcanic eruption to

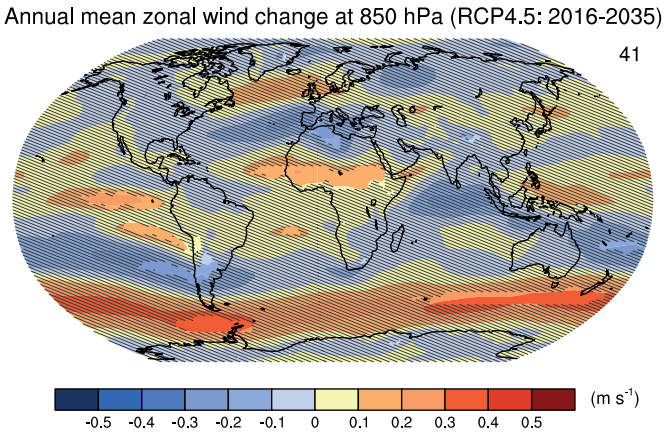

Figure 11.15 | CMIP5 multi-model ensemble mean of projected changes (m s^{-1}) in zonal (west-to-east) wind at 850 hPa for 2016–2035 relative to 1986–2005 under RCP4.5. The number of CMIP5 models used is indicated in the upper right corner. Hatching and stippling as in Figure 11.10.

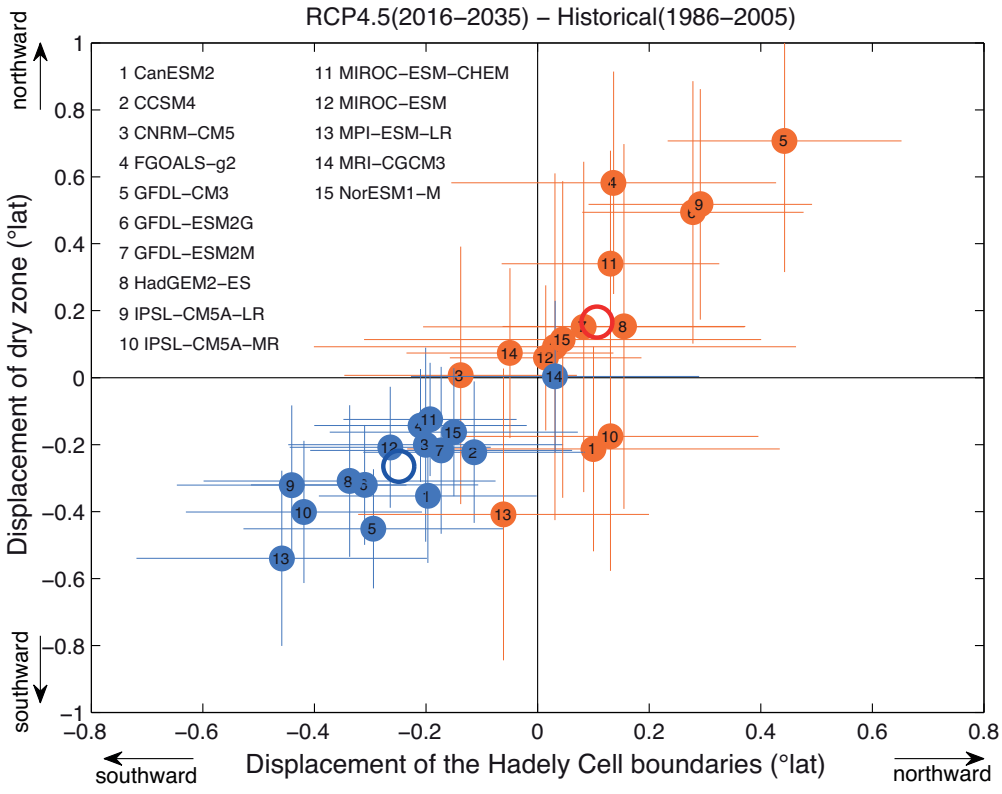

Figure 11.16 | Projected changes in the annual averaged poleward edge of the Hadley Circulation (horizontal axis) and sub-tropical dry zones (vertical axis) based on 15 Atmosphere–Ocean General Circulation Models (AOGCMs) from the CMIP5 (Taylor et al., 2012) multi-model ensemble, under 21st century RCP4.5. Orange symbols show the change in the northern edge of the Hadley Circulation/dry zones, while blue symbols show the change in the southern edge of the Hadley Circulation/dry zones. Open circles indicate the multi-model average, while horizontal and vertical coloured lines indicate the ±1 standard deviation range for internal climate variability estimated from each model. Values referenced to the 1986–2005 climatology. (Figure based on the methodology of Lu et al., 2007.)

contraction of the tropics and the tropical circulation (Lu et al., 2007; Birner, 2010). So future solar variations and volcanic activities could also lead to variations in the width of the Hadley Cell. The poleward extent of the Hadley Circulation and associated dry zones can exhibit substantial internal variability (e.g., Birner, 2010; Davis and Rosenlof, 2012) that can be as large as its near-term projected changes (Figure 11.16). There is also considerable uncertainty in the amplitude of the poleward shift of the Hadley Circulation in response to GHGs across multiple AOGCMs (Lu et al., 2007; Figure 11.16). It is *likely* that the poleward extent of the Hadley Circulation will increase through the mid-21st century. However, because of the counteracting impacts of future changes in stratospheric ozone and GHG concentrations, it is *unlikely* that it will continue to expand poleward in the SH as rapidly as it did in recent decades.

The Hadley Cell expansion in the NH has been largely attributed to the low-frequency variability of the SST (Hu et al., 2013), the increase of black carbon (BC) and tropospheric ozone (Allen and Sherwood, 2011). Internal variability in the poleward edge of the NH Hadley Circulation is large relative the radiatively forced signal (Figure 11.16. Given the complexity in the forcing mechanism of the NH expansion and the uncertainties in future concentrations of tropospheric pollutants, there is *low confidence* in the character of near-term changes to the structure of the NH Hadley Circulation.

Global climate models and theoretical considerations suggest that a warming of the tropics should lead to a weakening of the zonally asymmetric or Walker Circulation (Knutson and Manabe, 1995; Held and Soden, 2006; Vecchi and Soden, 2007; Gastineau et al., 2009). Aerosol forcing can modify both Hadley and Walker Circulations, which—depending on the details of the aerosol forcing—may lead to temporary reversals or enhancements in any GHG-driven weakening of the Walker Circulation (Sohn and Park, 2010; Bollasina et al., 2011; Merrifield, 2011; DiNezio et al., 2013). Meanwhile, the strength and structure of the Walker Circulation are impacted by internal climate variations, such as the ENSO (e.g., Battistiand Sarachik, 1995), the PDO (e.g., Zhang et al. 1997) and the IPO (Power et al., 1999, 2006; Meehl and Hu, 2006; Meehl and Arblaster, 2011; Power and Kociuba, 2011b; Meehl and Arblaster, 2012; Meehl et al., 2013a). Even on time scales of 30 to 100 years, substantial variations in the strength of the Pacific Walker Circulation in the absence of changes in RF are possible (Power et al., 2006; Vecchi et al., 2006). Estimated near-term weakening of the Walker Circulation from CMIP3 models under the A1B scenario (Vecchi and Soden, 2007; Power and Kociuba, 2011a) are *very likely* to be smaller than the impact of internal climate variations over 50-year time scales (Vecchi et al., 2006). There is also considerable response uncertainty in the amplitude of the weakening of Walker Circulation in response to GHG increase across multiple AOGCMs (Vecchi and Soden, 2007; DiNezio et al., 2009; Power and Kociuba, 2011a, 2011b). Thus, there is *low confidence* in projected near-term changes to the Walker Circulation. It is *very likely* that there will be decades in which the Walker Circulation strengthens and weakens due to internal variability through the mid-century as the externally forced change is small compared to internally generated decadal variability.

11.3.2.5 Atmospheric Extremes

Extreme events in a changing climate are the subject of Chapter 3 (Seneviratne et al., 2012) of the IPCC Special Report on Extremes (SREX). This previous IPCC chapter provides an assessment of more than 1000 studies. Here the focus is on near-term aspects and an assessment of more recent studies is provided.

11.3.2.5.1 Temperature extremes

In the AR4 (Meehl et al., 2007b), cold episodes were projected to decrease significantly in a future warmer climate and it was considered *very likely* that heat waves would be more intense, more frequent and last longer towards the end of the 21st century. These conclusions have generally been confirmed in subsequent studies addressing both global scales (Clark et al., 2010; Diffenbaugh and Scherer, 2011; Caesar and Lowe, 2012; Orlowsky and Seneviratne, 2012; Sillmann et al., 2013) and regional scales (e.g., Gutowski et al., 2008; Alexander and Arblaster, 2009; Fischer and Schar, 2009; Marengo et al., 2009; Meehl et al., 2009a; Diffenbaugh and Ashfaq, 2010; Fischer and Schar, 2010; Cattiaux et al., 2012; Wang et al., 2012). In the SREX assessment it is

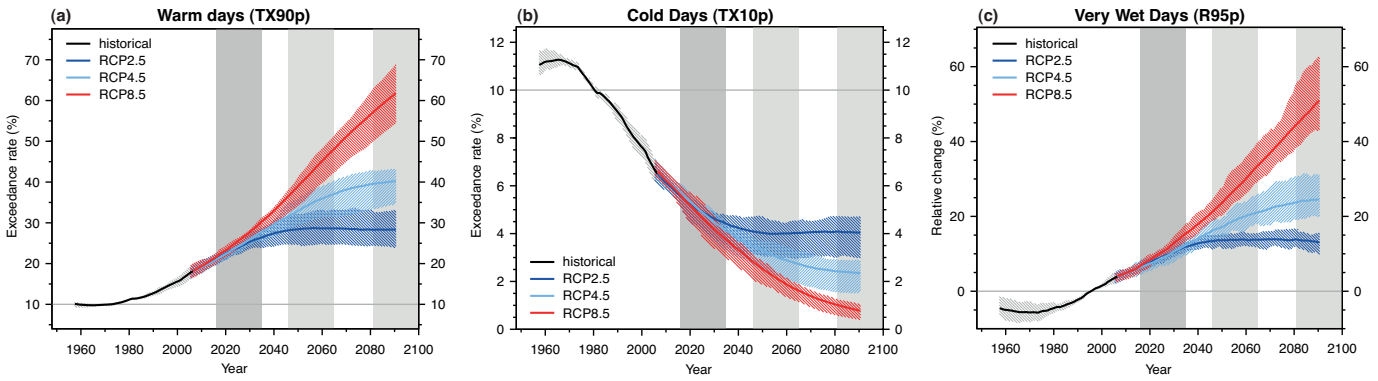

Figure 11.17 | Global projections of the occurrence of (a) warm days (TX90p), (b) cold days (TX10p) and (c) precipitation amount from very wet days (R95p). Results are shown from CMIP5 for the RCP2.6, RCP4.5 and RCP8.5 scenarios. Solid lines indicate the ensemble median and shading indicates the interquartile spread between individual projections (25th and 75th percentiles). The specific definitions of the indices shown are (a) percentage of days annually with daily maximum surface air temperature (T_{max}) exceeding the 90th percentile of T_{max} for 1961–1990, (b) percentage of days with T_{max} below the 10th percentile and (c) percentage change relative to 1986–2005 of the annual precipitation amount from daily events above the 95th percentile. (From Sillmann et al., 2013.)

concluded that increases in the number of warm days and nights and decreases in the number of cold days and nights are *virtually certain* on the global scale.

None of the aforementioned studies specifically addressed the near term. However, detection and attribution studies (see also Chapter 10) show that temperature extremes have already increased in many regions, consistent with climate change projections, and analyses of CMIP5 global projections show that this trend will continue and become more notable. The CMIP5 model ensemble exhibits a significant decrease in the frequency of cold nights, an increase in the frequency of warm days and nights and an increase in the duration of warm spells (Sillmann et al., 2013). These changes are particularly evident in global mean projections (see Figure 11.17). Figure 11.17 shows that for the next few decades—as discussed in the introduction to the current chapter—these changes are remarkably insensitive to the emission scenario considered (Caesar and Lowe, 2012). In most land regions and in the near-term, the frequency of warm days and warm nights will thus *likely* continue to increase, while that of cold days and cold nights will *likely* continue to decrease.

Near-term projections from General Circulation Model–Regional Climate Model (GCM–RCM) model chains (van der Linden and Mitchell, 2009) for Europe are shown in Figure 11.18, displaying near-term changes in mean and extreme temperature (left-hand panels) and precipitation (right-hand panels) relative to the reference period 1986–2005. In terms of mean June, July and August (JJA) temperatures (Figure 11.18a), projections show a warming of 0.6°C to 1.5°C, with highest changes over the land portion of the Mediterranean. The north–south gradient in the projections is consistent with the AR4. Daytime extreme summer temperatures in southern and central Europe are projected to warm substantially faster than mean temperatures (compare Figure 11.18a and b). This difference between changes in mean and extremes can be explained by increases in interannual and/or synoptic variability, or increases in diurnal temperature range (Gregory and Mitchell, 1995; Schar et al., 2004; Fischer and Schar, 2010; Hansen, 2012; Quesada et al., 2012; Seneviratne et al., 2012). There is some evidence, however, that this effect is overestimated in some of the models (Fischer et al., 2012; Stegehuis et al., 2012), leading to a potential overestimation of the projected Mediterranean summer mean warming (Buser et al., 2009; Boberg and Christensen, 2012). With regard to near-term projections of

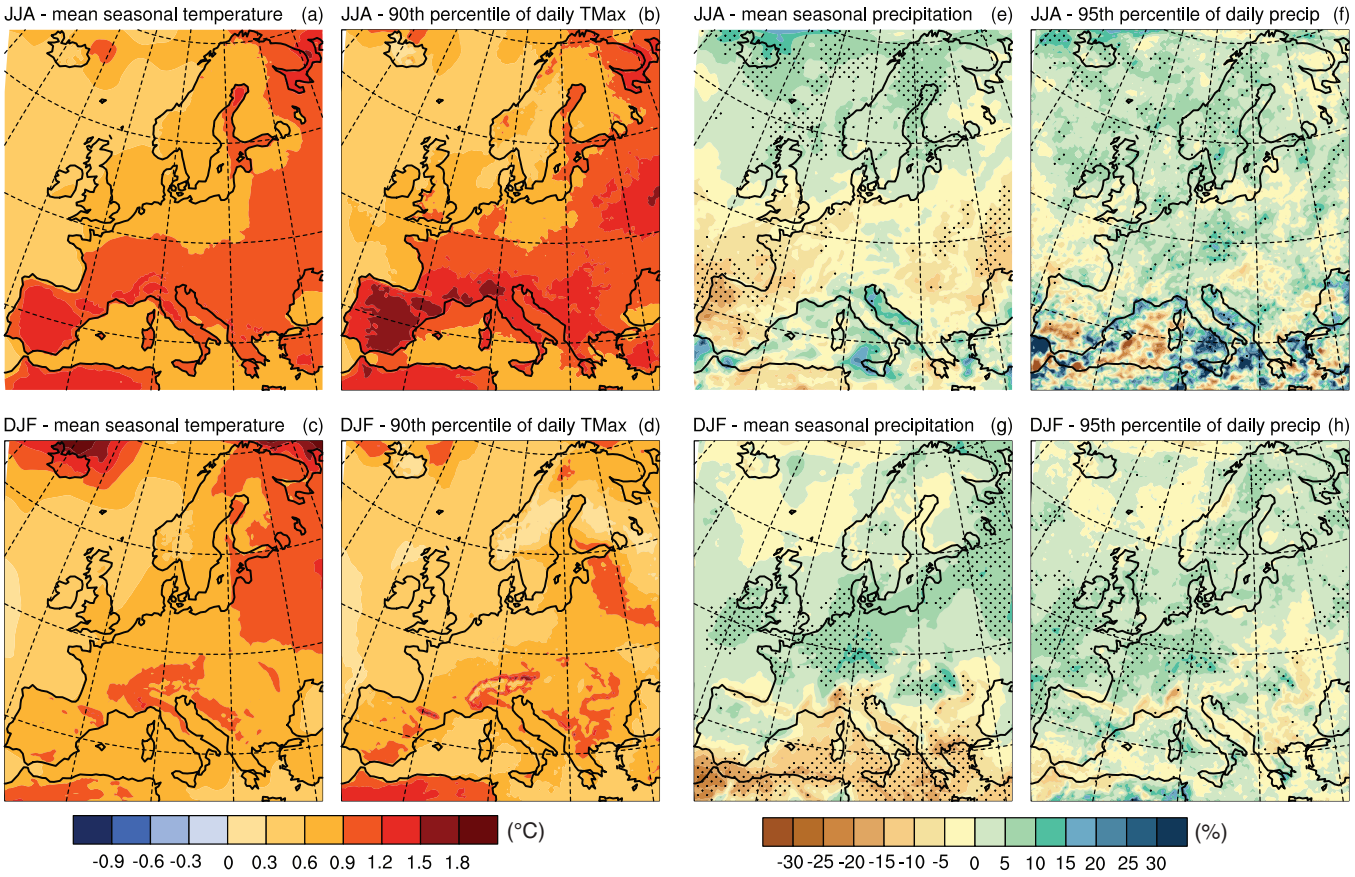

Figure 11.18 | European-scale projections from the ENSEMBLES regional climate modelling project for 2016–2035 relative to 1986–2005, with top and bottom panels applicable to June, July and August (JJA) and December, January, February (DJF), respectively. For temperature, projected changes (°C) are displayed in terms of ensemble mean changes of (a, c) mean seasonal surface temperature, and (b, d) the 90th percentile of daily maximum temperatures. For precipitation, projected changes (%) are displayed in terms of ensemble mean changes of (e, g) mean seasonal precipitation and (f, h) the 95th percentile of daily precipitation. The stippling in (e–h) highlights regions where 80% of the models agree in the sign of the change (for temperature all models agree on the sign of the change). The analysis includes the following 10 GCM-RCM simulation chains for the SRES A1B scenario (naming includes RCM group and GCM simulation): HadRM3Q0-HadCM3Q0, ETHZ-HadCM3Q0, HadRM3Q3-HadCM3Q3, SMHI-HadCM3Q3, HadRM3Q16-HadCM3Q16, SMHI-BCM, DMI-ARPEGE, KNMI-ECHAM5, MPI-ECHAM5, DMI-ECHAM5. (Rajczak et al., 2013.)

record heat compared to record cold (Meehl et al., 2009b) show, for one model, that over the USA the ratio of daily record high temperatures to daily record low temperatures could increase from an early 2000s value of roughly 2 to 1 to a mid-century value of about 20 to 1.

In terms of December, January and February (DJF) temperatures (Figure 11.18c), projections show a warming of 0.3°C to 1.8°C, with the largest changes in the N–NE part of Europe. This characteristic pattern of changes tends to persist to the end of century (van der Linden and Mitchell, 2009). In contrast to JJA temperatures, daytime high-percentile (i.e., warm) winter temperatures are projected to warm slower than mean temperatures (compare Figure 11.18c and Figure 11.18d), while low-percentile (i.e., cold) winter temperatures warm faster than the mean. This behaviour is indicative of reductions in internal variability, which may be linked to changes in storm track activity, reductions in diurnal temperature range and changes in snow cover (e.g., Colle et al. 2013; Dutra et al., 2011).

11.3.2.5.2 Heavy precipitation events

For the 21st century, the AR4 and the SREX concluded that heavy precipitation events were *likely* to increase in many areas of the globe (IPCC, 2007). Since AR4, a larger number of additional studies have been published using global and regional climate models (Fowler et al., 2007; Gutowski et al., 2007; Sun et al., 2007; Im et al., 2008; O'Gorman and Schneider, 2009; Xu et al., 2009; Hanel and Buishand, 2011; Heinrich and Gobiet, 2011; Meehl et al., 2012b). For the near term, CMIP5 global projections (Figure 11.17c) confirm a clear tendency for increases in heavy precipitation events in the global mean, but there are significant variations across regions (Sillmann et al., 2013). Past observations have also shown that interannual and decadal variability in mean and heavy precipitation are large, and are in addition strongly affected by internal variability (e.g., El Niño), volcanic forcing and anthropogenic aerosol loads (see Section 2.3.1). In general models have difficulties in representing these variations, particularly in the tropics (see Section 9.5.4.2). Thus the frequency and intensity of heavy precipitation events will *likely* increase over many land areas in the near term, but this trend will not be apparent in all regions, because of natural variability and possible influences of anthropogenic aerosols.

Simulations with regional climate models demonstrate that the response in terms of heavy precipitation events to anthropogenic climate change may become evident in some but not all regions in the near term. For instance, ENSEMBLES projections for Europe (see Figure 11.18e–h) confirm the previous IPCC results that changes in mean precipitation as well as heavy precipitation events are characterized by a pronounced north–south gradient in the extratropics, especially in the winter season, with precipitation increases in the higher latitudes and decreases in the subtropics. Although this pattern starts to emerge in the near term, the projected changes are statistically significant only in a fraction of the domain. The results are affected by both changes in water vapour content as induced by large-scale warming and large-scale circulation changes. Figure 11.18e–h also shows that mid- and high-latitude projections for changes in DJF extremes and means are qualitatively similar in the near term, at least for the event size considered.

Previous work reviewed in AR4 has established that extreme precipitation events may increase substantially stronger than mean precipitation amounts. More specifically, extreme events may increase with the atmospheric water vapour content, that is, up to the rate of the Clausius–Clapeyron (CC) relationship (e.g., Allen and Ingram, 2002). More recent work suggests that increases beyond this threshold may occur for short-term events associated with thunderstorms (Lenderink and Van Meijgaard, 2008; Lenderink and Meijgaard, 2010) and tropical convection (O'Gorman, 2012). A number of studies showed strong dependencies on location and season, but confirm the existence of significant deviations from the CC scaling (e.g., Lenderink et al., 2011; Mishra et al., 2012; Berg et al., 2013). Studies with cloud-resolving models generally support the existence of temperature-precipitation relations that are close to or above (up to about twice) the CC relation (Muller et al., 2011; Singleton and Toumi, 2012).

11.3.2.5.3 Tropical cyclones

The projected response of tropical cyclones (TCs) at the end of the 21st century is summarized in Section 14.6.1 and the IPCC Special Report on Extremes (SREX) (Seneviratne et al., 2012). Relative to the number of studies focussing on projections of TC activity at the end of the 21st century (Section 14.6.1; Knutson et al., 2010; Seneviratne et al., 2012 there are fewer studies that have explored near-term projections of TC activity (Table 11.2); the North Atlantic (NA) stands out as the basin with most studies. In the NA, there are mixed projections for basin-wide TC frequency, suggesting significant decreases (Knutson et al., 2013a) or non-significant changes (Villarini et al., 2011; Villarini and Vecchi, 2012). Multi-model mean projected NA TC frequency changes based on CMIP3 and CMIP5 over the first half of the 21st century were smaller than the overall uncertainty estimated from the Coupled General Circulation Models (CGCMs), with internal climate variability being a leading source of uncertainty through the mid-21st century (Villarini et al., 2011; Villarini and Vecchi, 2012). Therefore, based on the limited literature available, the conflicting near-term projections in basins with more than one study, the large influence of internal variability, the lack of confidently detected/attributed changes in TC activity (Chapter 10) and the conflicting projections for basin-wide TC frequency even at the end of the 21st century (Chapter 14), there is currently *low confidence* in basin-scale and global projections of trends in tropical cyclone frequency to the mid-21st century.

Exploring different hurricane intensity measures, two studies project near-term increases of NA hurricane intensity (Knutson et al., 2013a; Villarini and Vecchi, 2013), driven in large part by projected reductions in NA tropospheric aerosols in CMIP5 future forcing scenarios. Studies project near-term increases in the frequency Category 4–5 TCs in the NA (Knutson et al., 2013a) and southwest Pacific (Leslie et al., 2007). Published studies agree in the sign of projected mid-century intensity change (intensification), but the only basin with more than one study exploring intensity is the NA. For the NA, an estimate of the time scale of emergence of projected changes in intense TC frequency exceeds 60 years (Bender et al., 2010), although that estimate depends crucially on the amplitude of internal climate variations of intense hurricane frequency (e.g., Emanuel, 2011), which remains poorly constrained at the moment. Therefore, there is *low confidence* in near-term TC intensity projections in all TC basins.

Table 11.2 | Summary of studies exploring near-term projections of tropical cyclone (TC) activity. First column lists the TC basin explored, the second column summarizes the changes in TC activity reported in each study, the third column presents notes on the methodology and the fourth column provides a reference to the study.

TC Basin Explored	Projected Change in TC Activity Reported	Notes	Reference
Global	Reduced global, Northern Hemisphere and Southern Hemisphere frequency 2016–2035 relative to 1986–2005.	High-resolution atmospheric model forced by CMIP3 SRES A1B multi-model SST change 2004–2099.	Sugi and Yoshimura (2012)
N.W. Pacific	Over first half of 21st century: Reduced Activity over South China Sea, Increased Activity near subtropical Asia	Statistical downscale of five CMIP3 models under SRES A1B.	Wang et al. (2011)
N.W. Pacific	Over 2001–2040, a decrease in TC frequency in the East China Sea, and a frequency decrease and increase in intensity of Yangze River Basin landfalling typhoons.	Statistical downscaling of CGCM forced by CMIP3 SRES A1B scenario.	Orlowsky and Seneviratne (2012)
S.W. Pacific	Differences of 2000–2050 with 1970–2000. Negligible change in overall frequency. Significant (~15%) increase in number of Category 4–5 TCs.	Dynamical regional downscale of coupled AOGCM forced with IPCC IS92a increasing CO_2 scenario.	Leslie et al. (2007)
N. Atlantic	Linear trend in TC frequency 2001–2050: Ensemble-mean non-significant decrease in TC frequency (–5%). Ensemble range of –50% to +30%.	Statistical downscaling of CMIP3 models under A1B scenario.	Villarini et al. (2011)
N. Atlantic	TC frequency averaged 2016–2035 minus 1986–2005: Ensemble-mean non-significant increase for RCP2.6 (4%), non-significant decrease for RCP4.5 (–2%) and RCP8.5 (–1%). Ensemble range of –30% to 27% across all scenarios/models.	Statistical downscaling of CMIP5 RCP2.6, RCP4.5 and RCP8.5	Villarini and Vecchi (2012)
N. Atlantic	Power Dissipation Index averaged 2016–2035 minus 1986–2005: Ensemble mean significant increase for RCP2.6 (23%) and RCP8.5 (17%), non-significant increase for RCP4.5 (10%). Ensemble range of –43% to 78% across all scenarios/models.	Statistical downscaling of CMIP5 RCP2.6, RCP4.5 and RCP4.5	Villarini and Vecchi (2013)
N. Atlantic	Difference 2016–2035 minus 1986–2005 averages: Significant decrease (–20%) to overall TC and hurricane frequency. Significant increase (+45%) in number of Category 4–5 TCs. Significant increase in precipitation of hurricanes (11%) and tropical storms (18%).	Double dynamical refinement of CMIP5 RCP4.5 multi-model ensemble projections.	Knutson et al. (2013a)

Modes of climate variability that in the past have led to variations in the intensity, frequency and structure of tropical cyclones across the globe—such as the ENSO (e.g., Zhang and Delworth, 2006; Wang et al., 2007; Callaghan and Power, 2011; Chapter 14)—are *very likely* to continue influencing TC activity through the mid-21st century. Therefore, it is *very likely* that over the next few decades tropical cyclone frequency, intensity and spatial distribution globally, and in individual basins, will vary from year to year and decade to decade.

11.3.3 Near-term Projected Changes in the Ocean

11.3.3.1 Temperature

Globally averaged surface and near-surface ocean temperatures are projected by AOGCMs to warm over the early 21st century, in response to both present day atmospheric concentrations of GHGs ('committed warming'; e.g., Meehl et al., 2006) and projected future changes in RF (Figure 11.19). Globally averaged SST shows substantial year-to-year and decade-to-decade variability (e.g., Knutson et al., 2006; Meehl et al., 2011), whereas the variability of depth-averaged ocean temperatures is much less (e.g., Meehl et al., 2011; Palmer et al., 2011). The rate at which globally averaged surface and depth-averaged temperatures rise in response to a given scenario for RF shows a considerable spread between models (an example of response uncertainty; see Section 11.2), due to differences in climate sensitivity and ocean heat uptake (e.g., Gregory and Forster, 2008). In the CMIP5 models under all RCP forcing scenarios, globally averaged SSTs are projected to be warmer over the near term relative to 1986–2005 (Figure 11.20).

A key uncertainty in the future evolution of globally averaged oceanic temperature are possible future large volcanic eruptions, which could impact the radiative balance of the planet for 2 to 3 years after their eruption and act to reduce oceanic temperature for decades into the future (Delworth et al., 2005; Stenchikov et al., 2009; Gregory, 2010). An estimate using the GFDL-CM2.1 coupled AOGCM (Stenchikov et al., 2009) suggests that a single Tambora (1815)-like volcano could erase the projected global ocean depth-averaged temperature increase for many years to a decade. A Pinatubo (1991)-like volcano could erase the projected increase for 2 to 10 years. See Section 11.3.6 for further discussion.

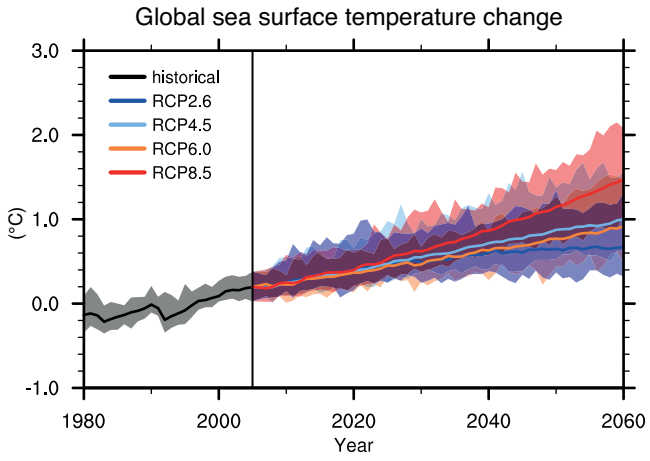

Figure 11.19 | Projected changes in annual averaged, globally averaged, surface ocean temperature based on 12 Atmosphere–Ocean General Circulation Models (AOGCMs) from the CMIP5 (Meehl et al., 2007b) multi-model ensemble, under 21st century scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5. Shading indicates the 90% range of projected annual global mean surface temperature anomalies. Anomalies computed against the 1986–2005 average from the historical simulations of each model.

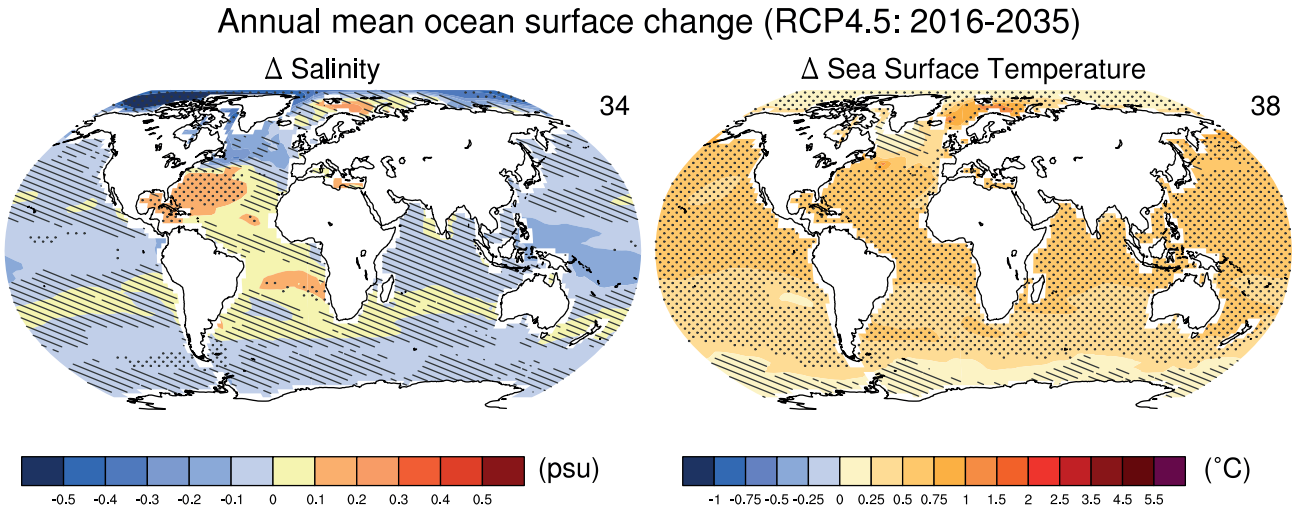

Figure 11.20 | CMIP5 multi-model ensemble mean of projected changes in sea surface temperature (right panel; °C) and sea surface salinity (left panel; practical salinity units) for 2016–2035 relative to 1986–2005 under RCP4.5. The number of CMIP5 models used is indicated in the upper right corner. Hatching and stippling as in Figure 11.10.

In the absence of multiple major volcanic eruptions (see Section 11.3.6.2), it is *very likely* that globally averaged surface and depth-averaged temperatures averaged 2016–2035 will be warmer than those averaged over 1986–2005.

There are regional variations in the projected amplitude of ocean temperature change (Figure 11.20) which are influenced by ocean circulation as well as surface heating (Timmermann et al., 2007; Vecchi and Soden, 2007; DiNezio et al., 2009; Yin et al., 2009; Xie et al., 2010; Yin et al., 2010), including changes in tropospheric aerosol concentrations (e.g., Booth et al., 2012; Villarini and Vecchi, 2012). Inter-decadal variability of upper ocean temperatures is larger in mid-latitudes, particularly in the NH, than in the tropics. A consequence of this contrast is that it will take longer in the mid-latitudes than in the tropics for the anthropogenic warming signal to emerge from the noise of internal variability (Wang et al., 2010).

Projected changes to thermal structure of the tropical Indo-Pacific are strongly dependent on the future behaviour of the Walker Circulation (Vecchi and Soden, 2007; DiNezio et al., 2009; Timmermann et al., 2010), in addition to changes in heat transport and changes in surface heat fluxes. It is *likely* that internal climate variability will be a dominant contributor to changes in the depth and tilt of the equatorial thermocline, and the strength of the east–west gradient of SST across the Pacific through the mid-21st century; thus it is *likely* there will be multi-year periods with increases or decreases in these measures.

11.3.3.2 Salinity

Changes in sea surface salinity are expected in response to changes in precipitation, evaporation and runoff (see Section 11.3.2.3), as well as ocean circulation; in general (but not in every region), salty regions are expected to become saltier and fresh regions fresher (e.g., Durack et al. 2012; Terray et al. 2012; Figure 11.20). As discussed in Chapter 10 (Section 10.4.2), observation-based and attribution studies have found some evidence of an emerging anthropogenic signal in salinity change (Section 10.4.2), in particular increases in surface salinity in the subtropical North Atlantic, and decreases in the west Pacific warm pool region (Stott et al., 2008; Cravatte et al., 2009; Durack and Wijffels, 2010; Durack et al., 2012; Pierce et al., 2012; Terray et al., 2012). Models generally predict increases in salinity in the tropical and (especially) subtropical Atlantic, and decreases in the western tropical Pacific over the next few decades (Figure 11.20) (Durack et al., 2012; Terray et al., 2012). These projected decreases in the Atlantic and in the western tropical Pacific are considered *likely*.

Projected near-term increases in freshwater flux into the Arctic Ocean produce a fresher surface layer and increased transport of fresh water into the North Atlantic (Holland et al., 2006; Holland et al., 2007; Vavrus et al., 2012). Such contributions to decreased density of the ocean surface layer in the North Atlantic could act to reduce deep ocean convection there and contribute to a near-term reduction of strength of Atlantic Meridional Ocean Circulation (AMOC). However, the strength of the AMOC can also be modulated by changes in temperature, such as those from changing RF (Delworth and Dixon, 2006).

11.3.3.3 Circulation

As discussed in previous assessment reports, the AMOC is generally projected to weaken over the next century in response to increase in atmospheric GHG. However, the rate and magnitude of weakening is very uncertain. Response uncertainty is a major contributor in the near term, but the influence of anthropogenic aerosols and natural RFs (solar, volcanic) cannot be neglected, and could be as important as the influence of GHGs (e.g., Delworth and Dixon, 2006; Stenchikov et al., 2009). For example, the rate of weakening of the AMOC in two models with different climate sensitivities is quite different, with the less sensitive model (CCSM4) showing less weakening and a more rapid recovery than the more sensitive model (Community Earth System Model 1/Community Atmosphere Model 5 (CESM1/CAM5; Meehl et al., 2013c). In addition, the natural variability of the AMOC on decadal time scales is poorly known and poorly understood, and could dominate any anthropogenic response in the near term (Drijfhout and Hazeleger, 2007). The AMOC is known to play an important role in the

decadal variability of the North Atlantic Ocean, but climate models show large differences in their simulation of both the amplitude and spectrum of AMOC variability (e.g., Bryan et al., 2006; Msadek et al., 2010). In some AOGCMs changes in SH surface winds influence the evolution of the AMOC on time scales of many decades (Delworth and Zeng, 2008), so the delayed response to SH wind changes, driven by the historical reduction in stratospheric ozone along with its projected recovery, could be an additional confounding issue (Section 11.3.2.3). Overall, it is *likely* that there will be some decline in the AMOC by 2050, but decades during which the AMOC increases are also to be expected. There is *low confidence* in projections of when an anthropogenic influence on the AMOC might be detected (Baehr et al., 2008; Roberts and Palmer, 2012).

Projected changes to oceanic circulation in the Indo-Pacific are strongly dependent on future response of the Walker Circulation (Vecchi and Soden, 2007; DiNezio et al., 2009), the near-term projected weakening of which is smaller than the expected variability on time scales of decades to years (Section 11.3.2.4.3). Taking variability into account, there is *medium confidence* in a weakening of equatorial Pacific circulation, including equatorial upwelling and the shallow subtropical overturning in the Pacific, and the Indonesian Throughflow over the coming decades.

11.3.4 Near-term Projected Changes in the Cryosphere

This section assesses projected near-term changes of elements of the cryosphere. These consist of sea ice, snow cover and near-surface permafrost (frozen ground), changes to the Arctic Ocean and possible abrupt changes involving the cryosphere. Glaciers and ice sheets are addressed in Chapter 13. Here near-term changes in the geographical coverage of sea ice, snow cover and near-surface permafrost are assessed.

Trends due to changes in external forcing exist alongside considerable interannual and decadal variability. This complicates our ability to make specific, precise short-term projections, and delays the emergence of a forced signal above the noise.

11.3.4.1 Sea Ice

Though most of the CMIP5 models project a nearly ice-free Arctic (sea ice extent less than 1×10^6 km^2 for at least 5 consecutive years) at the end of summer by 2100 in the RCP8.5 scenario (see Section 12.4.6.1), some show large changes in the near term as well. Some previous models project an ice-free summer period in the Arctic Ocean by 2040 (Holland et al., 2006), and even as early as the late 2030s using a criterion of 80% sea ice area loss (e.g., Zhang, 2010). By scaling six CMIP3 models to recent observed September sea ice changes, a nearly ice-free Arctic in September is projected to occur by 2037, reaching the first quartile of the distribution for timing of September sea ice loss by 2028 (Wang and Overland, 2009). However, a number of models that have fairly thick Arctic sea ice produce a slower near-term decrease in sea ice extent compared to observations (Stroeve et al., 2007). Based on a linear extrapolation into the future of the recent sea ice volume trend from a hindcast simulation conducted with a regional model of the Arctic sea ice–ocean system (Maslowski et al., 2012) projected that it would take only until about 2016 to reach a nearly ice-free Arctic Ocean in summer. However, such an approach not only neglects the effect of year-to-year or longer-term variability (Overland and Wang, 2013) but also ignores the negative feedbacks that can occur when the sea ice cover becomes thin (Notz, 2009). Mahlstein and Knutti (2012) estimated the annual mean global surface warming threshold for nearly ice-free Arctic conditions in September to be ~2°C above the present derived from both CMIP3 models and observations.

An analysis of CMIP3 model simulations indicates that for near-term predictions the dominant factor for decreasing sea ice is increased ice melt, and reductions in ice growth play a secondary role (Holland et al., 2010). Arctic sea ice has larger volume loss when there is thicker ice initially across the CMIP3 models, with a projected accumulated mass loss of about 0.5 m by 2020, and roughly 1.0 m by 2050, with considerable model spread (Holland et al., 2010). The CMIP3 models tended to under-estimate the observed rapid decline of summer Arctic sea ice during the satellite era, but these recent trends are more accurately simulated in the CMIP5 models (see Section 12.4.6.1). For CMIP3 models, results indicate that the changes in Arctic sea ice mass budget over the 21st century are related to the late 20th century mean sea ice thickness distribution (Holland et al., 2010), average sea ice thickness (Bitz, 2008; Hodson et al., 2012), fraction of thin ice cover (Boe et al., 2009) and oceanic heat transport to the Arctic (Mahlstein et al., 2011). Acceleration of sea ice drift observed over the last three decades, underestimated in CMIP3 projections (Rampal et al., 2011), and the presence of fossil-fuel and biofuel soot in the Arctic environment (Jacobson, 2010), could also contribute to ice-free late summer conditions over the Arctic in the near term. Details on the transition to an ice-free summer over the Arctic are presented in Chapter 12 (Sections 12.4.6.1 and 12.5.5.7).

The discussion in Section 12.4.6.1 makes the case for assessing near-term projections of Arctic sea ice by weighting/recalibrating the models based on their present-day Arctic sea ice simulations, with a credible underlying physical basis in order to increase confidence in the results, and accounting for the potentially large imprint of natural variability on both observations and model simulations (see Section 9.8.3). A subselection of a set of CMIP5 models that fits those criteria, following the methodology proposed by Massonnet et al. (2012), is applied in Chapter 12 (Section 12.4.6.1) to the full set of models that provided the CMIP5 database with sea ice output. Among the five selected models, four project a nearly ice-free Arctic Ocean in September (sea ice extent less than 1×10^6 km^2 for at least 5 consecutive years) before 2050 for RCP8.5, the earliest and latest years of near disappearance of the sea ice pack being about 2040 and about 2060, respectively. The potential irreversibility of the Arctic sea ice loss and the possibility of an abrupt transition toward an ice-free Arctic Ocean are discussed in Section 12.5.5.7.

In light of all these results and others discussed in greater detail in Section 12.4.6.1, it is *very likely* that the Arctic sea ice cover will continue to shrink and thin all year round during the 21st century as the annual mean global surface temperature rises. It is also *likely* that the Arctic Ocean will become nearly ice-free in September before the middle of the century for high GHG emissions such as those corresponding to RCP8.5 (*medium confidence*).

In early 21st century simulations, Antarctic sea ice cover is projected to decrease in the CMIP5 models, though CMIP3 and CMIP5 models simulate recent decreases in Antarctic sea ice extent compared to slight increases in the observations (Section 12.4.6.1). However, there is the possibility that melting of the Antarctic ice sheet could be changing the vertical ocean temperature stratification around Antarctica and encourage sea ice growth (Bintanja et al., 2013). This and other evidence discussed in Section 12.4.6.1 leads to the assessment that there is *low confidence* in Antarctic sea ice model projections that show near-term decreases of sea ice cover because of the wide range of model responses and the inability of almost all of the models to reproduce the mean seasonal cycle, interannual variability and overall increase of the Antarctic sea ice areal coverage observed during the satellite era (see Section 9.4.3).

11.3.4.2 Snow Cover

Decreases of snow cover extent (SCE, defined over ice-free land areas) are strongly connected to a shortening of seasonal snow cover duration (Brown and Mote, 2009) and are related to both precipitation and temperature changes (see Section 12.4.6.2). This has implications for snow on sea ice where loss of sea ice area in autumn delays snowfall accumulation, with CMIP5 multi-model mean values of snow depth in April north of 70°N reduced from about 28 cm to roughly 18 cm for the 2031–2050 period compared to the 1981–2000 average (Hezel et al., 2012). The snow accumulation season by mid-century in one model is projected to begin later in autumn, with the melt season initiated earlier in the spring (Lawrence and Slater, 2010). As discussed in greater detail in Section 12.4.6.2, projected increases in snowfall across much of the northern high latitudes act to increase snow amounts, but warming reduces the fraction of precipitation that falls as snow. In addition, the reduction of Arctic sea ice also provides an increased moisture source for snowfall (Liu et al., 2012). Whether the average SCE decreases or increases by mid-century depends on the balance between these competing factors. The dividing line where models transition from simulating increasing or decreasing maximum snow water equivalent roughly coincides with the –20°C isotherm in the mid-20th century November to March mean surface air temperature (Raisanen, 2008). The projected change of SCE over some regions is inconsistent with that of extreme snowfall, a major contributor to SCE. For instance, SCE is projected to decrease over northern China by the mid-21st century (Shi et al., 2011), while the extreme snowfall events over the region are projected to increase (Sun et al., 2010).

Time series of projected changes in relative SCE (for NH ice-free land areas) are shown in Figure 12.32. Multi-model averages from the CMIP5 archive (Brutel-Vuilmet et al., 2013) show percentage decreases of NH SCE ± 1 standard deviation for the 2016–2035 time period for a March to April average using a 15% extent threshold for the four RCP scenarios as follows: RCP2.6: –5.2% ± 1.9% (21 models); RCP4.5: –5.3% ± 1.5% (24 models); RCP6.0: –4.5% ± 1.2% (16 models); RCP8.5: –6.0% ± 2.0% (24 models).

11.3.4.3 Near Surface Permafrost

Virtually all near-term projections indicate a substantial amount of near-surface permafrost degradation (typically taking place in the upper 2 to 3 m; see Callaghan et al. (2011) and see glossary for detailed definition), and thaw depth deepening over much of the permafrost area (Sushama et al., 2006; Lawrence et al., 2008; Guo and Wang, 2012). As discussed in more detail in Section 12.4.6.2, these projections have increased credibility compared to the previous generation of models assessed in the AR4 because current climate models represent permafrost more accurately (Alexeev et al., 2007; Nicolsky et al., 2007; Lawrence et al., 2008). The reduction in annual mean near-surface permafrost area for the 2016–2035 time period compared to the 1986–2005 reference period for the CMIP5 models (Slater and Lawrence, 2013) for the NH for the four RCP scenarios is 21% ± 5% (RCP2.6), 18% ± 6% (RCP4.5), 18% ± 3% (RCP6.0) and 20% ± 5% (RCP8.5).

11.3.5 Projections for Atmospheric Composition and Air Quality to 2100

The future evolution of atmospheric composition is determined by the chemical–physical processes in the atmosphere, forced primarily by anthropogenic and natural emissions and by interactions with the biosphere and ocean (Chapters 2, 6, 7, 8 and 12). Twenty-first century projections of the chemically reactive GHGs, including methane (CH_4), nitrous oxide (N_2O) and ozone (O_3), as well as aerosols, are assessed here (Section 11.3.5.1). Future air pollution, specifically ground-level O_3 and $PM_{2.5}$ (particulate matter with a diameter of less than 2.5 µm, a measure of aerosol concentration), is also assessed here (Section 11.3.5.2). The impact of changes in natural emissions and deposition through altered land use (Heald et al., 2008; Chen et al., 2009a; Cook et al., 2009; Wu et al., 2012) and production of food or biofuels (Chapter 6) on atmospheric composition and air quality are not assessed here. Projected CO_2 abundances are discussed in Chapters 6 and 12.

Projections for the 21st century are based predominantly on the CMIP5 models that included atmospheric chemistry and the related ACCMIP (Atmospheric Chemistry and Climate Model Intercomparison Project) models, driven by the RCP emission and climate scenarios. These and the earlier SRES scenarios include only direct anthropogenic emissions. Natural emissions may also change with biosphere feedbacks in response to climate or land use change (Chapters 6, 8). Emphasis is placed on evaluating the 21st-century RCP scenarios from emissions to abundance, summarized in tables in Annex II. For the well-mixed greenhouse gases (WMGHGs), the effective radiative forcing (ERF) in both RCP and SRES scenarios increases similarly before 2040 with little spread (±16% in ERF; see Tables AII.6.1 to AII.6.10), but by 2050 the RCP2.6 scenario diverges, falling well below the envelope containing both the SRES and other RCP scenarios.

National and regional regulations implemented on emissions contributing to ground-level ozone and $PM_{2.5}$ pollution influence global atmospheric chemistry and climate (NRC, 2009; HTAP, 2010a), as was recognized in the TAR (Jacob et al., 1993; Penner et al., 1993; Johnson et al., 1999; Prather et al., 2001). Ozone and aerosols are radiatively active species (Chapters 7 and 8) and many of their precursors serve as indirect GHGs (e.g., nitrogen oxides (NO_x), carbon monoxide (CO), Non Methane Volatile Organic Compounds (NMVOC)) by changing the atmospheric oxidative capacity, and thereby the lifetimes and abundances of CH_4, hydrofluorocarbons (HFCs) and tropospheric O_3 (Chapter 8). Consequently their evolution can influence near-term climate

both regionally and globally (Section 11.3.6.1 and FAQ 8.2). The RCP and SRES scenarios differ greatly in terms of the short-lived air pollutants and aerosol climate forcing. The CMIP3 climate simulations driven by the SRES scenarios projected a wide range of future air pollutant trajectories, including unconstrained growth that resulted in very large tropospheric O_3 increases (Prather et al., 2003). Subsequently, the near-term projections of current legislation (CLE) and maximum feasible reductions (MFR) emissions illustrated the impacts of air pollution control strategies on air quality, global atmospheric chemistry and near-term climate (Dentener et al., 2005, 2006; Stevenson et al., 2006). The RCP scenarios applied in the CMIP5 climate models all assume a continuation of current trends in air pollution policies (van Vuuren et al., 2011) and thus do not cover the range of future pollutant emissions found in the literature, specifically those with higher pollutant emissions (Dentener et al., 2005; Kloster et al., 2008; Pozzer et al., 2012); see Chapter 8.

The new RCP emissions are compared to the older SRES and other published emission scenarios in Annex II (Tables AII.2.1 to AII.2.22) and Figures 8.2 and 8.SM.1. By 2030 the RCP aerosol and ozone precursor emissions are smaller than SRES by factors of 1.2 to 3. For these short-lived air pollutants, the spread across RCPs by 2030 is much smaller than the range between the CLE and MFR scenarios: ±12% vs. ±31% for nitrogen oxides; ±17% vs. ±60% for sulphate; ±5% vs. ±11% for carbon monoxide. BC aerosol emissions also vary little across the RCPs: ±4% range in 2030; ±15% in 2100. Most of this spread is due to uncertain projections for the rapidly industrializing nations. From 2000 to 2030, sulphur dioxide (SO_2) emissions decline in the RCPs by –15% to –8% per decade, within the range of the MFR and CLE scenarios (–23% to +2% per decade), but far below the SRES range (+4% to +21% per decade). Evaluation of recent trends in SO_2 emissions shows a trend similar to the near-term RCP projections (Smith et al., 2011; Klimont et al., 2013), but independent estimates for recent trends in other aerosol species are not available. The RCP trend in NO_x emissions (–5% to +2% per decade) is likewise within the CLE-MFR range, but far below the SRES trends (+10% to +30% per decade). For OC and BC emissions, the RCP trend lies between the SRES B1/A2 range. A simple sum of the main four aerosol emissions (N, S, OC, BC; Tables AII.2.18 to AII.2.22) in the SRES vs. RCP scenarios indicates that the CMIP3 simulations driven by the SRES scenarios have about 40% more aerosols in 2000 than the CMIP5 simulations driven by the RCP scenarios. On average, these aerosols increase by 9% per decade in the SRES scenarios but decrease by 5% per decade in the RCP scenarios over the near term. By 2030, the CMIP3 models thus include up to three times more anthropogenic aerosols under the SRES scenarios than the CMIP5 models driven by the RCP scenarios (*high confidence*).

11.3.5.1 Reactive Greenhouse Gases and Aerosols

The IPCC has assessed previous emission-based scenarios for future GHGs and aerosols in the SAR (IS92) and TAR/AR4 (SRES). The new RCP scenarios are different in that they embed a simple, parametric model of atmospheric chemistry and biogeochemistry that maps emissions onto atmospheric abundances (the 'concentration pathways') (Lamarque et al., 2011; Meinshausen et al., 2011a, 2011b; van Vuuren et al., 2011). As an integrated product, the RCP-prescribed emissions, abundances and RF used in the CMIP5 model ensembles do not reflect the current best understanding of natural and anthropogenic emissions, atmospheric chemistry and biogeochemistry and RF of climate (Chapters 2, 6 and 8) (see, e.g., Dlugokencky et al., 2011; Prather et al., 2012; Lamarque et al., 2013; Stevenson et al., 2013; Voulgarakis et al., 2013; Young et al., 2013). Rather, the best estimates of atmospheric abundances and associated RF include a more complete atmospheric chemistry description and a fuller set of uncertainties than considered in the RCPs provided to the CMIP5 models. While this widens the range of climate forcing for each individual scenario, this uncertainty generally remains smaller than the range across the four RCP scenarios.

11.3.5.1.1 Methane, nitrous oxide and the fluorinated gases

Kyoto GHG abundances projected to year 2100 are given in Annex II (Tables AII.4.1–AII.4.15) as both RCP published values (Meinshausen et al., 2011b) and derived from the RCP anthropogenic emissions pathways. The latter includes current best estimates of atmospheric chemistry and natural sources, with uncertainties (denoted RCP$^{\&}$). Emissions of CH_4 and N_2O, primarily from the agriculture, forestry and other land use sectors (AFOLU) are uncertain, typically by 25% or more (Prather et al., 2009; NRC, 2010). Following the method of Prather et al. (2012) a best estimate and uncertainty range for the year 2011 anthropogenic and natural emissions of CH_4 and N_2O are derived using updated AR5 values (see Chapters 2, 5 and 6). The re-scaled RCP$^{\&}$ anthropogenic-only emissions of CH_4 and N_2O are given in Tables AII.2.2 and AII.2.3 and differ from the published RCPs by a single scale factor for each species. An uncertainty range for 2011 values (*likely*, ±1 standard deviation in %, based on Prather et al. 2012) is applied to all subsequent years. Abundances are then integrated using these rescaled RCP$^{\&}$ anthropogenic emissions, the best estimate for natural emissions, and a model projecting changes in tropospheric OH (see Holmes et al., 2013; for details). Similar scaling to match current observational constraints (harmonization) was done for the SRES emissions (Prather et al., 2001) and the RCPs (Meinshausen et al., 2011b). However, these earlier harmonizations used older values for lifetimes and natural sources, and did not provide estimates of uncertainty.

Combining CH_4 observations, lifetime estimates for the present day, the ACCMIP studies, plus estimated limits on changing natural sources, gives a year 2011 total anthropogenic CH_4 emission of 354 ± 45 $Tg(CH_4)\ yr^{-1}$ (Montzka et al., 2011; Prather et al., 2012) (Chapters 2, 6 and 8). The RCP total emission lies within 10% of this value, and thus the scaling factor between the RCP$^{\&}$ and RCP total emission, is small (Table AII.2.2). Projection of the tropospheric OH lifetime of CH_4 (AII.5.8) is based on the ACCMIP simulations of the RCPs for 2100 time slice simulations (Voulgarakis et al., 2013), other modelling studies (Stevenson et al., 2006; John et al., 2012) and multi-model sensitivity analyses of key factors (Holmes et al., 2013) that includes uncertainties in emissions from agricultural, forest and land use sources, in atmospheric lifetimes, and in chemical feedbacks and loss. Lifetimes, and thus future CH_4 abundances, decrease slowly under RCP2.6 and RCP4.5, remain almost constant under RCP6.0 and increase slowly under RCP8.5. Future changes in natural sources of CH_4 due to land use and climate change are included in a few CMIP5 models and may alter future CH_4 abundances (Chapter 6), but there is limited evidence, and thus these changes are not included in the RCP$^{\&}$ projections.

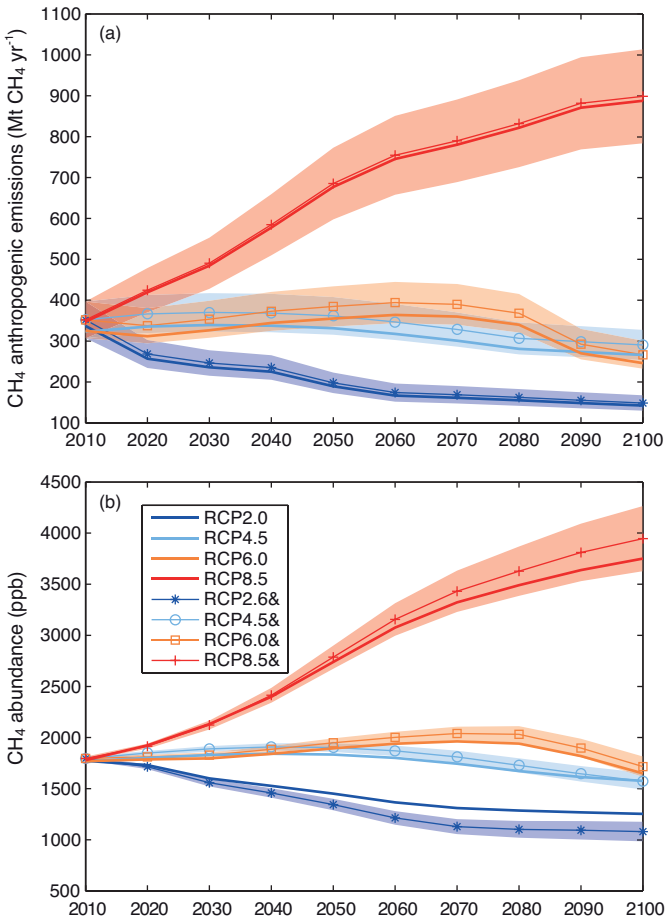

Figure 11.21 | Projections for CH_4 (a) anthropogenic emissions ($MtCH_4\ yr^{-1}$) and (b) atmospheric abundances (ppb) for the four RCP scenarios (2010–2100). Natural emissions in 2010 are estimated to be 202 ± 35 $MtCH_4\ yr^{-1}$ (see Chapter 8). The thick solid lines show the published RCP2.6 (light blue), RCP4.5 (dark blue), RCP6.0 (orange) and RCP8.5 (red) values. Thin lines with markers show values from this assessment (denoted as RCPn.n&, following methods of Prather et al. (2012) and Holmes et al. (2013): red plus, RCP8.5; orange square, RCP6.0; light blue circle, RCP4.5; dark blue asterisk, RCP2.6. The shaded region shows the *likely* range from the Monte Carlo calculations that consider uncertainties, including in current anthropogenic emissions.

The resulting best estimates of total CH_4 anthropogenic emissions and abundances (RCP&) are compared with RCP values in Figure 11.21. For RCP2.6, the CH_4 abundance is projected to decline continuously over the century by about 30%, whereas in RCP 4.5 and 6.0 it peaks mid-century and then declines to below the year 2011 abundance by the end of the century. Throughout the century, the uncertainty in CH_4 abundance for an individual scenario is less than range from RCP2.6 to RCP8.5. For example, by year 2020 the spread in CH_4 abundance across the RCPs is already large, 1720 to 1920 ppb, with uncertainty in each scenario estimated at only ±20 ppb. The *likely* range for RCP& CH_4 is 30% wider than that in the RCP CH_4 abundances used to force the CMIP5 models (Figure 11.21): by year 2100 the *likely* range of RCP8.5& CH_4 abundance extends 520 ppb above the single-valued RCP8.5 CH_4 abundance, and RCP2.6& CH_4 extends 230 ppb below RCP2.6 CH_4.

Substantial effort has gone into identifying and quantifying individual sources of N_2O (see Chapter 6) but less into evaluating its lifetime and chemical feedbacks. Recent multi-model, chemistry–climate studies (CCMVal) project a more vigorous stratospheric overturning by 2100 that is expected to shorten the N_2O lifetime (Oman et al., 2010; Strahan et al., 2011), but no evaluation of the lifetime is reported. Here we combine observations of N_2O (pre-industrial, present, and present trends; Chapter 2), with two modern studies of the lifetime (Hsu and Prather, 2010; Fleming et al., 2011), and a Monte Carlo method (Prather et al., 2012) to estimate a year 2011 total anthropogenic emission of 6.7 ± 1.3 $TgN(N_2O)\ yr^{-1}$ (Table AII.2.3). All RCP N_2O (anthropogenic) emissions are reduced by 20% so that year 2011 values are consistent with an observationally constrained budget using a longer lifetime than adopted by the RCPs (Table AII.2.3). The N_2O lifetime (Table AII.5.9) is projected to decrease by 2 to 4% by year 2100, due to changing circulation and chemistry in the stratosphere (Fleming et al., 2011) and to the negative chemical feedback on its own lifetime (Prather and Hsu, 2010). In the near term, the spread in N_2O across RCP&s is small: 330 to 332 ± 4 ppb in year 2020; 346 to 365 ± 11 ppb in year 2050. By year 2100, the range of best-estimate N_2O concentrations across the RCP&s (354–425 ppb) is 20% smaller than that across the RCPs (344–435 ppb), but the *likely* range in RCP&s encompasses the RCP range.

Recent measurements show some discrepancies with bottom-up inventories of the industrially produced, synthetic fluorinated (F) gases (AII.2.4 to AII.2.15). European HFC-23 emissions are greatly under-reported (Keller et al., 2011) while HFC-125 and 152a are roughly consistent with emissions inventories (Brunner et al., 2012). Globally, HFC-365mfc and HFC-245fa emissions are overestimated (Vollmer et al., 2011) while SF_6 appears to be under-reported (Levin et al., 2010). For HFC-134a, combining current measurements and lifetimes (Table 2.1, Chapter 8; WMO, 2010; Prather et al., 2012) gives an estimate of 2010 emissions (~150 Gg yr^{-1}) that is consistent with the RCP range (139 to 153 Gg yr^{-1}). Without clear guidance on how to correct or place uncertainty on the RCP F-gas emissions, the RCP emissions are reported without uncertainty estimates in Annex II Tables AII.2.4 to AII.2.15. For the very long-lived SF_6 and perfluorocarbons (CF_4, C_2F_6, C_6F_{10}) uncertainty in lifetimes does not significantly affect the projected abundances over the 21st century (AII.4.4 to AII.4.7). Projected HFC abundances depend on the changes in tropospheric OH, which determines their atmospheric lifetime (Chapter 8). The relative change in hydroxyl radical (OH), as indicated by the projected OH lifetime of CH_4 (AII.5.8), is used to project HFCs including uncertainties (*likely* range) (AII.4.8 to AII.4.15) (Prather et al., 2012).

Scenarios for the ozone-depleting GHG under control of the Montreal Protocol (chlorofluorocarbons (CFCs), HCFCs, halons in AII.4.16) follow scenario A1 of the 2010 WMO Ozone Assessment (WMO, 2010; Table 5-A3). All CFC abundances decline throughout the century, but some HCFC abundances increase to 2030 before their phase-out and decline. The summed ERF of all these F-gases is approximately constant (0.35 to 0.39 W m^{-2}) up to year 2040 for all RCPs but declines thereafter. In RCP8.5, the drop in ERF from the Montreal Protocol gases is nearly made up by the growth in HFCs (Tables AII.6.4 to AII.6.6, Chapter 8).

11.3.5.1.2 Tropospheric and stratospheric O_3

Projected O_3 changes are broken into tropospheric and stratospheric columns (Dobson Unit (DU); see AII.5.1 and AII.5.2) because each has different driving factors and RF efficiencies (Chapter 8). Tropospheric

O_3 changes are driven by anthropogenic emissions of CH_4, NO_x, CO, NMVOC (AII.2.2.16 to AII.2.2.18). Small changes (<10%) are projected over the next few decades. By 2100 tropospheric O_3 decreases in RCP2.6, 4.5 and 6.0 but increases in RCP8.5 due to CH_4 increases. Higher tropospheric temperatures and humidity drive a decline in tropospheric O_3, but stratospheric O_3 recovery and increased stratosphere–troposphere exchange can counter that (Shindell et al., 2006; Zeng et al., 2008, 2010; Kawase et al., 2011; Lamarque et al., 2011). The latter effect is difficult to quantify but it is included in some of the ACCMIP and CMIP5 models used to project tropospheric O_3. Changes in natural emissions of NO_x, particularly soil and lightning NO_x, and biogenic NMVOC may also alter tropospheric O_3 abundances (Wild, 2007; Wu et al., 2007). However, global estimates of their change with climate (e.g., Kesik et al., 2006; Monson et al., 2007; Butterbach-Bahl et al., 2009; Price, 2013) remain highly uncertain.

Best estimates for projected tropospheric O_3 change following the RCP scenarios (Table AII.5.2) are based on ACCMIP time slice simulations for 2030 and 2100 with chemistry–climate models (Young et al., 2013) and the CMIP5 simulations (Eyring et al., 2013). There is *high confidence* in these results because similar estimates are obtained when projections are made using the response of tropospheric O_3 to key forcing factors that vary across scenarios (Prather et al., 2001; Stevenson et al., 2006; Oman et al., 2010; Wild et al., 2012). The ACCMIP models show a wide range in tropospheric O_3 burden changes from 2000 to 2100: –5 DU (–15%) in RCP2.6 to +5 DU in RCP8.5. The CMIP5 results are similar but not identical: –3 DU (–9%) to +10 DU (+30%). The 2030 and 2100 multi-model mean estimates are more robust for ACCMIP which includes 5 to 11 models (range depends on time slice and scenario) than for CMIP5 (4 models). Tropospheric O_3 changes in the near term (2030–2040) are small (±2 DU), except for RCP8.5 (>3 DU), which shows continued growth through to 2100 driven primarily by CH_4 increases. The ERF from tropospheric O_3 changes (AII.6.7b) parallels the O_3 burden change (Stevenson et al., 2013).

Stratospheric O_3 is being driven by declining chlorine levels, changing N_2O and CH_4, cooler temperatures from increased CO_2, and a more vigorous overturning circulation in the stratosphere driven by more wave propagation under climate change (Butchart et al., 2006; Eyring et al., 2010; Oman et al., 2010). Overall stratospheric O_3 is expected to increase in the coming decades, reversing the majority of the loss that occurred between 1980 and 2000. Best estimates for global mean stratospheric O_3 change under the RCP scenarios (Table AII.5.1) are taken from the CMIP5 results (Eyring et al., 2013). By 2100 stratospheric O_3 columns show a 5 to 7% increase above 2000 levels for all RCPs, recovering to within 1% of the pre-ozone hole 1980 levels by 2050, but with latitudinal differences.

11.3.5.1.3 Aerosols

Aerosol species can be emitted directly (mineral dust, sea salt, BC and some organic carbon (OC)) or indirectly through precursor gases (SO_2, ammonia, nitrogen oxides, hydrocarbons); see Chapter 7. CMIP5 models (Lamarque et al., 2011; Shindell et al., 2013) have projected changes in aerosol burden (Tg) and aerosol optical depth (AOD) to year 2100 using RCP emissions for anthropogenic source (Tables AII.5.3 to AII.5.8). Total AOD is dominated by dust and sea salt, but absorbing aerosol optical depth (AAOD) is primarily of anthropogenic origin (Chapter 7). Uniformly, anthropogenic aerosols decrease under RCPs as expected from the declining emissions (11.3.5, Figure 8.2, AII.2.17 to AII.2.22). From years 2010 to 2030 the aerosol burdens decrease across the RCPs but at varied rates: for sulphate from 6% (RCP8.5) to 23% (RCP2.6); for BC from 5% (RCP4.5) to 15% (RCP2.6), and for OC from 0% (RCP6.0) to 11% (RCP4.5). The summed aerosol loading of these three anthropogenic components drop from year 2010 to year 2030 by 5% to 12% (across RCPs), and by year 2100 this drop is 24% to 39% (Tables AII.5.5 to AII.5.7). These evolving aerosol loadings reduce the magnitude of the negative aerosol forcing (Chapter 8; Table AII.6.9) even in the near term (11.3.6.1).

11.3.5.2 Projections of Air Quality for the 21st Century

Future air quality depends on anthropogenic emissions (local, regional and global), natural biogenic emissions and the physical climate (e.g., Steiner et al., 2006, 2010; Meleux et al., 2007; Tao et al., 2007; Wu et al., 2008; Doherty et al., 2009; Carlton et al., 2010; Tai et al., 2010; Hoyle et al., 2011). This assessment focuses on O_3 and $PM_{2.5}$ in surface air, reflecting the preponderance of published literature and multi-model assessments for these air pollutants (e.g., HTAP, 2010a) plus the chemistry–climate CMIP5 and ACCMIP model simulations. Nitrogen and acid deposition is addressed in Chapter 6. Toxic atmospheric species such as mercury and persistent organic pollutants are outside this assessment (Jacob and Winner, 2009; NRC, 2009; HTAP, 2010b, 2010c).

The global and continental-scale surface O_3 and $PM_{2.5}$ changes assessed here include (1) the impact of climate change (Section 11.3.5.2.1), and (2) the impact of changing global and regional anthropogenic emissions (Section 11.3.5.2.2). Changes in local emissions within a metropolitan region or surrounding air basin on local air quality projections are not assessed here. Anthropogenic emissions of O_3 precursors include NO_x, CH_4, CO, and NMVOC; $PM_{2.5}$ is both directly emitted (OC, BC) and produced photochemically from precursor emissions (NO_x, NH_3, SO_2, NMVOC) (see Tables AII.2.2,16-22). Recent reviews describe the impact of temperature-driven processes on O_3 and $PM_{2.5}$ air quality from observational and modelling evidence (Isaksen et al., 2009; Jacob and Winner, 2009; Fiore et al., 2012). Projecting future air quality empirically from a mean surface warming using the observed correlation with temperature is problematic, as there is little evidence that future pollution episodes can be simply modelled as all else being equal except for a uniform temperature shift. Air quality relationships with synoptic conditions may be more robust (e.g., Dharshana et al., 2010; Appelhans et al., 2012; Tai et al., 2012a, 2012b), but require the ability to project changes in key conditions such as blocking and stagnation episodes. The response of blocking frequency to global warming is complex, with summertime increases possible over some regions, but models are generally biased compared to observed blocking statistics, and indicate even larger uncertainty in projecting changes in blocking intensity and persistence (Box 14.2).

11.3.5.2.1 Climate-driven changes

Projecting regional air quality faces the challenge of simulating first the changes in regional climate and then the feedbacks from atmospheric chemistry and the biosphere. The air pollution response

to climate-driven changes in the biosphere is uncertain as to sign because of competing effects: for example, plants currently emit more NMVOC with warmer temperatures; with higher CO_2 and water stress plants may emit less; with a warmer climate the vegetation types may shift to emit either more or less NMVOC; shifting vegetation types may also alter surface uptake of ozone and aerosols; and our understanding of chemical oxidation pathways for biogenic emissions is incomplete (e.g., Monson et al., 2007; Carlton et al., 2009; Hallquist et al., 2009; Ito et al., 2009; Pacifico et al., 2009, 2012; Paulot et al., 2009). Although studies have split the cause of air quality changes into climate versus emissions, these attributions are difficult to assess for several reasons: the global-to-regional down-scaling of meteorology that is model dependent (see Chapters 9 and 14; also Manders et al., 2012), the brief simulations that preclude clear separation of climate change from climate variability (Nolte et al., 2008; Fiore et al., 2012; Langner et al., 2012a), and the lack of systematically explored standard scenarios for local anthropogenic emissions, land use change and biogenic emissions.

Ozone

Globally, a warming climate decreases baseline surface O_3 almost everywhere but increases O_3 levels in some polluted regions and seasons. The surface ozone response to climate change alone between 2000 and 2030 is shown in Figure 11.22 (CLIMATE), where the ranges reflect multi-model differences in spatial averages (solid green lines) and spatial variability within a single model (dashed green lines). There is *high confidence* that in unpolluted regions, higher water vapour abundances and temperatures enhance O_3 destruction, leading to lower baseline O_3 levels in a warmer climate (e.g., global average in Figure 11.22). Higher CH_4 levels such as in RCP8.5 can offset this climate-driven decrease in baseline O_3. Other large-scale factors that could increase baseline O_3 in a warming climate include increased lightning NO_x and stratospheric influx of O_3 (see Section 11.3.5.1). Evidence and agreement are limited regarding the impact of climate change on long-range transport of pollutants (Wu et al., 2008; HTAP, 2010a; Doherty et al., 2013). The global chemistry-climate models assessed here (Figures 11.22, 11.23ab) include most of these feedback processes, but a systematic evaluation of their relative impacts is lacking.

In polluted regions, observations show that high-O_3 episodes correlate with high temperatures (e.g., Lin et al., 2001; Bloomer et al., 2009; Rasmussen et al., 2012), but these episodes also coincide with cloud-free enhanced photochemistry and with air stagnation that concentrates pollution near the surface (e.g., AR4 Box 7.4). Other temperature-related factors, such as biogenic emissions from vegetation and soils, volatilization of NMVOC, thermal decomposition of organic nitrates to NO_x and wildfire frequency may increase with a warming climate and are expected to increase surface O_3 (e.g., Doherty et al., 2013; Skjøth and Geels, 2013; and as reviewed by Isaksen et al. (2009), Jacob and Winner (2009) and Fiore et al. (2012)), although some of these processes are known to have optimal temperature ranges (e.g., Sillman and Samson, 1995; Guenther et al., 2006; Steiner et al., 2010). Overall, the integrated effect of these processes on O_3 remains poorly understood, and they have been implemented with varying levels of complexity in the models assessed here.

Models show that a warmer atmosphere can lead to local O_3 increases during the peak pollution season (e.g., by 2 to 6 ppb within Central Europe by 2030; green dashed line for Europe in Figure 11.22). Regional models projecting summer daytime statistics tend to simulate a wider range of climate-driven changes (e.g., Zhang et al., 2008; Avise et al., 2012; Kelly et al., 2012), with most studies focusing on 2050 (Fiore et al., 2012) or beyond. For example, summer temperature extremes over parts of Europe are projected to warm more than the corresponding mean local temperatures due to enhanced variability at interannual to intraseasonal time scales (see Section 12.4.3.3). Several modelling studies note a longer season for O_3 pollution in a warmer world (Nolte et al., 2008; Racherla and Adams, 2008). For some regions, models agree on the sign of the O_3 response to a warming climate (e.g., increases in northeastern USA and southern Europe; decreases in northern Europe), but they often disagree (e.g., the midwest, southeast, and western USA (Jacob and Winner, 2009; Weaver et al., 2009; Langner et al., 2012a; Langner et al., 2012b; Manders et al., 2012)). Several studies have suggested a role for changing synoptic meteorology on future air pollution levels (Leibensperger et al., 2008; Jacob and Winner, 2009; Weaver et al., 2009; Lang and Waugh, 2011; Tai et al., 2012a, 2012b; Turner et al., 2013), but projected regional changes in synoptic conditions are uncertain (see Sections 11.3.2.4, 12.4.3.3 and Box 14.2). Observational and modelling evidence together indicate that, all else being equal, a warming climate is expected to increase surface O_3 in polluted regions (*medium confidence*), although a systematic evaluation of all the factors driving extreme pollution episodes is lacking.

Aerosols

Evaluations as to whether climate change will worsen or improve aerosol pollution are model-dependent. Assessments are confounded by opposing influences on the individual species contributing to total $PM_{2.5}$ and large interannual variability caused by the small-scale meteorology (e.g., convection and precipitation) that controls aerosol concentrations (Mahmud et al., 2010). For a full discussion, see Chapter 7. Higher temperatures generally decrease nitrate aerosol through enhanced volatility but increase sulphate aerosol through faster production, although observed $PM_{2.5}$–temperature correlations also reflect humidity and synoptic meteorology (e.g., Aw and Kleeman, 2003; Liao et al., 2006; Racherla and Adams, 2006; Unger et al., 2006a; Hedegaard et al., 2008; Jacobson, 2008; Kleeman, 2008; Pye et al., 2009; Tai et al., 2012b). Natural aerosols may increase with temperature, particularly carbonaceous aerosol from wildfires, mineral dust, and biogenic secondary organic aerosol (SOA; Section 7.3.5; Mahowald and Luo, 2003; Tegen et al., 2004; Jickells et al., 2005; Woodward et al., 2005; Mahowald et al., 2006; Liao et al., 2007; Mahowald, 2007; Tagaris et al., 2007; Heald et al., 2008; Spracklen et al., 2009; Jiang et al., 2010; Yue et al., 2010; Carvalho et al., 2011; Fiore et al., 2012). SOA formation also depends on anthropogenic emissions and atmospheric oxidizing capacity (Carlton et al., 2010; Jiang et al., 2010).

Aerosols are scavenged from the atmosphere by precipitation and direct deposition (see Chapter 7). Hence most components of $PM_{2.5}$ are anti-correlated with precipitation (Tai et al., 2010), and aerosol burdens are expected to decrease on average where precipitation increases (Racherla and Adams, 2006; Liao et al., 2007; Tagaris et al., 2007; Zhang et al., 2008; Avise et al., 2009; Pye et al., 2009). However, a shift in the frequency and type of precipitation may be as important as the change in mean precipitation (see Chapter 7). Seasonal and regional

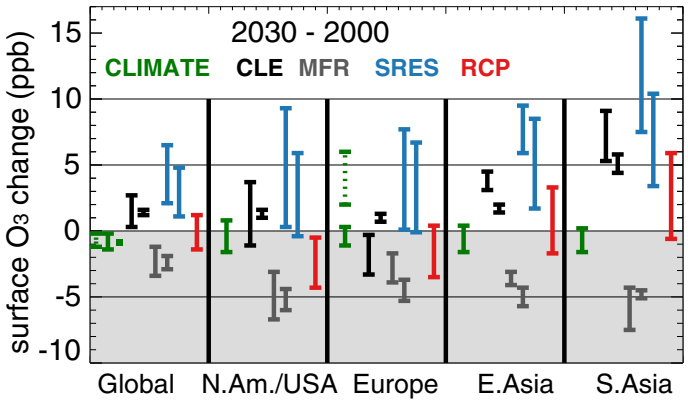

Figure 11.22 | Changes in surface O_3 (ppb) between year 2000 and 2030 driven by climate alone (CLIMATE, green) or driven by emissions alone, following current legislation (CLE, black), maximum feasible reductions (MFR, grey), SRES (blue) and RCP (red) emission scenarios. Results are reported globally and for the four northern mid-latitude source regions used by the Task Force on Hemispheric Transport of Air Pollution (HTAP, 2010a). Where two vertical bars are shown (CLE, MFR, SRES), they represent the multi-model standard deviation of the annual mean based on (left bar; SRES includes A2 only) the Atmospheric Composition Change: a European Network (ACCENT)/Photocomp study (Dentener et al., 2006) and (right bar) the parametric HTAP ensemble (Wild et al., 2012; four SRES and RCP scenarios included). Under Global, the leftmost (dashed green) vertical bar denotes the spatial range in climate-only changes from one model (Stevenson et al., 2005) while the green square shows global annual mean climate-only changes in another model (Unger et al., 2006b). Under Europe, the dashed green bar denotes the range of climate-only changes in summer daily maximum O_3 in one model (Forkel and Knoche 2006). (Adapted from Figure 3 of Fiore et al., 2012.)

differences in aerosol burdens versus precipitation further preclude a simple scaling of aerosol response to precipitation changes (Kloster et al., 2010; Fang et al., 2011). Climate-driven changes in the frequency of drizzle and the mixing depths or ventilation of the surface layer also influence projected changes in $PM_{2.5}$ (e.g., Kleeman, 2008; Dawson et al., 2009; Jacob and Winner, 2009; Mahmud et al., 2010), and aerosols in turn can influence locally clouds, precipitation and scavenging (e.g., Zhang et al., 2010b; see Section 7.6).

While $PM_{2.5}$ is expected to decrease in regions where precipitation increases, the climate variability at these scales results in only *low confidence* for projections at best. Further, consensus is lacking on the other factors including climate-driven changes in biogenic and mineral dust aerosols, leading to *no confidence level* being attached to the overall impact of climate change on $PM_{2.5}$ distributions.

11.3.5.2.2 Changes driven by regional and global anthropogenic pollutant emissions

Projections for annual-mean surface O_3 and $PM_{2.5}$ for 2000 through 2100 are shown in Figures 11.23a and 11.25b, respectively. Changes are spatially averaged over selected world (land-only) regions and include the combined effects of emission and climate changes under the RCPs. Results are taken from the ACCMIP models and a subset of the CMIP5 models that included atmospheric chemistry. Large interannual variations are evident in the CMIP5 transient simulations, and large regional variations occur in both the CMIP5 and the ACCMIP decadal time slice simulations (see Lamarque et al., (2013) for ACCMIP overview).

The largest surface O_3 changes under the RCP scenarios are much smaller than those projected under the older SRES scenarios (Figures 11.22 and 11.23a; Table AII.7; Lamarque et al., 2011; Wild et al., 2012). By 2100, global annual multi-model mean surface O_3 rises by 12 ppb in SRES A2, but by only 3 ppb in RCP8.5. Much larger O_3 decreases are projected to occur by 2030 under the MFR scenario (Figure 11.22), which assumes that existing control technologies are applied uniformly across the globe (Dentener et al., 2006).

For RCP2.6, RCP4.5 and RCP6.0, the CMIP5/ACCMIP models project that continental-scale spatially averaged near-term surface O_3 decreases or changes little (–4 to +1 ppb) from 2000 to 2030 for all regions except South Asia, whereas the long-term change to 2100 is a consistent decrease (–14 to –3 ppb) for all regions (Figure 11.23a; and Table AII.7.3). For RCP8.5, the CMIP5/ACCMIP models project continental-scale spatial average surface O_3 increases of up to +5 ppb for both 2030 and 2100 (Figure 11.23a; Table AII.7.3). The increases under RCP8.5 reflect the prominent rise in methane abundances (Kawase et al., 2011; Lamarque et al., 2011; Wild et al., 2012), which by 2100 raise background O_3 levels by 5 to 14 ppb over continental-scale regions, and on average by about 8 ppb (25% above current levels) above RCP4.5 and RCP6.0 which include more stable methane pathways over the 21st century (*high confidence*). Earlier studies have shown that rising CH_4 abundances (and global NO_x emissions) increase baseline O_3, and can offset aggressive local emission reductions and lengthen the O_3 pollution season (Jacob et al., 1999; Prather et al., 2001, 2003; Fiore et al., 2002, 2009; Hogrefe et al., 2004; Granier et al., 2006; Szopa et al., 2006; Tao et al., 2007; Huang et al., 2008; Lin et al., 2008; Wu et al., 2008; Avise et al., 2009; Chen et al., 2009b;HTAP, 2010a; Wild et al., 2012; Lei et al., 2013).

The O_3 changes driven by the RCP emissions scenarios with fixed, present-day climate (Figure 11.22; Wild et al., 2012) are similar to the changes estimated with the full chemistry–climate models (Figure 11.23a). Although the regions considered are not identical, the evidence supports a major role for global emissions in determining near-term O_3 concentrations. Overall, the multi-model ranges associated with the influence of near-term climate change on global and regional O_3 air quality are smaller than those across emission scenarios (Figure 11.22; HTAP, 2010a; Wild et al., 2012).

Aerosol changes driven by anthropogenic emissions depend somewhat on oxidant levels (e.g., Unger et al., 2006a; Kleeman, 2008; Leibensperger et al., 2011a), but generally sulphate follows SO_2 emissions and carbonaceous aerosols follow the primary elemental and OC emissions. Competition between sulphate and nitrate for ammonium (see Chapter 7) means that reducing SO_2 emissions while increasing NH_3 emissions as in the RCPs (Tables AII.2.19 and AII.2.20) would lead to near-term nitrate aerosol levels equal to or higher than those of sulphate in some regions; see Section 7.3.5.2 (Bauer et al., 2007; Pye et al., 2009; Bellouin et al., 2011; Henze et al., 2012).

Regional $PM_{2.5}$ in the CMIP5 and ACCMIP chemistry–climate models following the RCP scenarios generally declines over the 21st century, with little difference across the individual scenarios except for the South and East Asia regions (Figure 11.23b). The noisy projections over Africa, the Middle East and to some extent Australia, reflect dust

sources and their strong dependence on interannual meteorological variability. Over the two Asian regions, different $PM_{2.5}$ levels between the RCPs are due to (1) OC emission trajectories over South Asia and (2) combined changes in carbonaceous aerosol and SO_2 over East Asia (Fiore et al., 2012) (Figure 8.SM.1).

Global emissions of aerosols and precursors can contribute to high-PM events. For example, dust trans-oceanic transport events are observed to increase aerosols in downwind regions (Prospero, 1999; Grousset et al., 2003; Chin et al., 2007; Fairlie et al., 2007; Huang et al., 2008; Liu et al., 2009; Ramanathan and Feng, 2009; HTAP, 2010a). The balance between regional and global anthropogenic emissions versus climate-driven changes for $PM_{2.5}$ will vary regionally with future changes in precipitation, wildfires, dust and biogenic emissions.

In summary, lower air pollution levels are projected following the RCP emissions as compared to the SRES emissions in the TAR and AR4, reflecting implementation of air pollution control measures (*high confidence*). The range in projections of air quality is driven primarily by emissions (including CH_4) rather than by physical climate change (*medium confidence*). The total emission-driven range in air quality—including the CLE and MFR scenarios—is larger than that spanned by the RCPs (see Section 11.3.5.1 for comparison of RCPs and SRES).

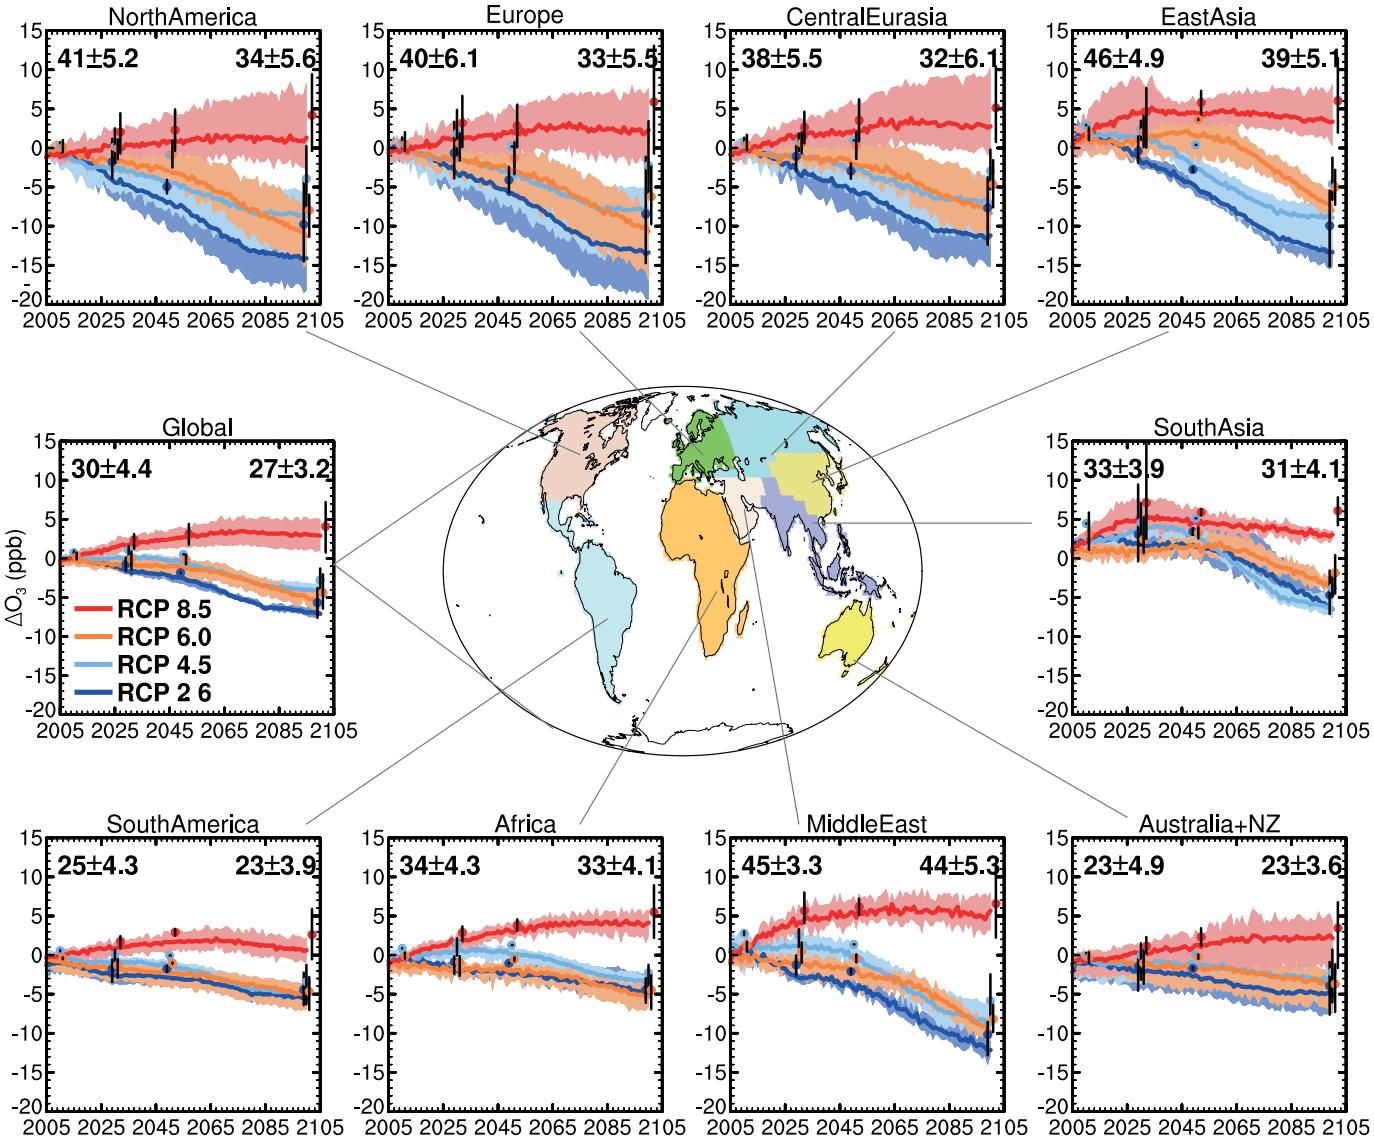

Figure 11.23a | Projected changes in annual mean surface O_3 (ppb mole fraction) from 2000 to 2100 following the RCP scenarios (8.5, red; 6.0, orange; 4.5, light blue; 2.6, dark blue). Results in each box are averaged over the designated coloured land regions. Continuous coloured lines and shading denote the average and full range of four chemistry–climate models (GFDL-CM3, GISS-E2-R, and NCAR-CAM3.5 from CMIP5 plus LMDz-ORINCA). Coloured dots and vertical black bars denote the average and full range of the ACCMIP models (CESM-CAM-superfast, CICERO-OsloCTM2, CMAM, EMAC-DLR, GEOSCCM, GFDL-AM3, HadGEM2, MIROC-CHEM, MOCAGE, NCAR-CAM3.5, STOC-HadAM3, UM-CAM) for decadal time slices centred on 2010, 2030, 2050 and 2100. Participation in the decadal slices ranges from 2 to 12 models (see (Lamarque et al., 2013)). Changes are relative to the 1986–2005 reference period for the CMIP5 transient simulations, and relative to the average of the 1980 and 2000 decadal time slices for the ACCMIP ensemble. The average value and model standard deviation for the reference period is shown in the top of each panel for CMIP5 models (left) and ACCMIP models (right). In cases where multiple ensemble members are available from a single model, they are averaged prior to inclusion in the multi-model mean. (Adapted from Fiore et al., 2012.)

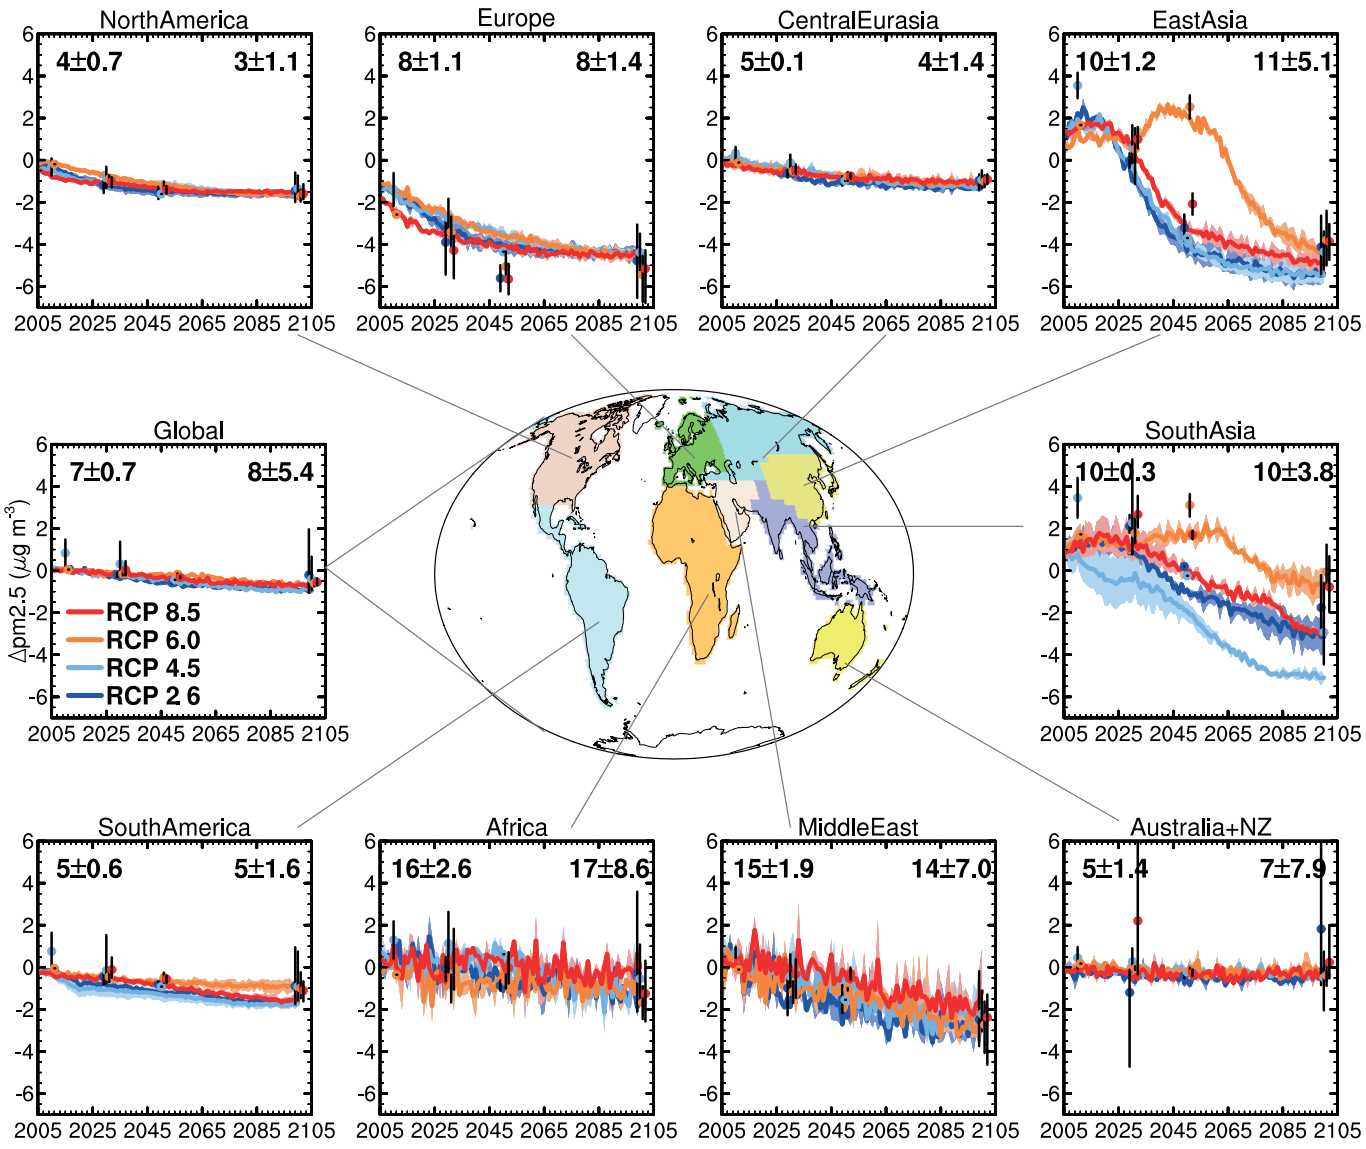

Figure 11.23b | Projected changes in annual mean surface $PM_{2.5}$ (micrograms per cubic metre of aerosols with diameter less than 2.5 μm) from 2000 to 2100 following the RCP scenarios (8.5 red, 6.0 orange, 4.5 light blue, 2.6 dark blue). $PM_{2.5}$ values are calculated as the sum of individual aerosol components (black carbon + organic carbon + sulphate + secondary organic aerosol + 0.1*dust + 0.25*sea salt). Nitrate was not reported for most models and is not included here. See Figure 11.23a for details, but note that fewer models contribute: GISS-E2-R and GFDL-CM3 from CMIP5; CICERO-OsloCTM2, GEOSCCM, GFDL-AM3, HadGEM2, MIROC-CHEM, and NCAR-CAM3.5 from ACCMIP. (Adapted from Fiore et al., 2012.)

11.3.5.2.3 Extreme weather and air pollution

Extreme air quality episodes are associated with changing weather patterns, such as heat waves and stagnation episodes (Logan, 1989; Vukovich, 1995; Cox and Chu, 1996; Mickley et al., 2004; Stott et al., 2004). Heat waves are generally associated with poor air quality (Ordóñez et al., 2005; Vautard et al., 2005; Lee et al., 2006b; Struzewska and Kaminski, 2008; Tressol et al., 2008; Vieno et al., 2010; Hodnebrog et al., 2012). Although anthropogenic climate change has increased the near-term risk of such heat waves (Stott et al., 2004; Clark et al., 2010; Diffenbaugh and Ashfaq, 2010; Chapter 10; Section 11.3.2.5.1), projected changes in the frequency of regional air stagnation events, which are largely driven by blocking events, remain difficult to assess: the frequency of blocking events with persistent high pressure is projected to decrease in a warming climate but increases may occur in some regions, and projected changes in their intensity and duration remain uncertain (Chapters 9 and 14; Box 14.2). Projections in regional air pollution extremes are necessarily conditioned on projected changes in these weather patterns. The severity of extreme pollution events also depends on local emissions (see references in Fiore et al., 2012). Feedbacks from vegetation (higher biogenic NMVOC emissions, lower stomatal uptake of O_3 with higher temperatures) can combine with similar positive feedbacks via dust and wildfires to worsen air pollution and its impacts during heat waves (Lee et al., 2006a; Jiang et al., 2008; Royal Society, 2008; Flannigan et al., 2009; Andersson and Engardt, 2010; Vieno et al., 2010; Hodnebrog et al., 2012; Jaffe and Wigder, 2012; Mues et al., 2012).

There is high agreement across numerous modelling studies projecting increases in extreme O_3 pollution events over the USA and Europe, but the projections do not consistently agree at the regional level (Kleeman, 2008; Jacob and Winner, 2009; Jacobson and Streets, 2009; Weaver et al., 2009; Huszar et al., 2011; Katragkou et al., 2011; Langner et al., 2012b) because they depend on accurate projections of local emissions, regional climate and poorly understood biospheric feedbacks. Although observational evidence clearly demonstrates a strong statistical correlation between extreme temperatures (heat waves) and pollution events, this temperature correlation reflects in part the coincident occurrence of stagnation events and clear skies that also drive extreme pollution. Mechanistic understanding of biogenic emissions, deposition and atmospheric chemistry is consistent with a temperature-driven increase in pollution extremes in already polluted regions, although these processes may not scale simply with mean temperature under a changing climate (see Section 11.3.5.2.1), and better projections of the changing meteorology at regional scales are needed. Assuming all else is equal (e.g., local anthropogenic emissions) this collective evidence indicates that uniformly higher temperatures in polluted environments will trigger regional feedbacks during air stagnation episodes that will increase peak pollution (*medium confidence*).

11.3.6 Additional Uncertainties in Projections of Near-term Climate

As discussed in Section 11.3.1, most of the projections presented in Sections 11.3.2 to 11.3.4 are based on the RCP4.5 scenario and rely on the spread among the CMIP5 ensemble of opportunity as an *ad hoc* measure of uncertainty. It is possible that the real world might follow a path outside (above or below) the range projected by the CMIP5 models. Such an eventuality could arise if there are processes operating in the real world that are missing from, or inadequately represented in, the models. Two main possibilities must be considered: (1) Future radiative and other forcings may diverge from the RCP4.5 scenario and, more generally, could fall outside the range of *all* the RCP scenarios; (2) The response of the real climate system to radiative and other forcing may differ from that projected by the CMIP5 models. A third possibility is that internal fluctuations in the real climate system are inadequately simulated in the models. The fidelity of the CMIP5 models in simulating internal climate variability is discussed in Chapter 9.

Future changes in RF will be caused by anthropogenic and natural processes. The consequences for near-term climate of uncertainties in anthropogenic emissions and land use are discussed in Section 11.3.6.1. The uncertainties in natural RF that are most important for near-term climate are those associated with future volcanic eruptions and variations in the radiation received from the Sun (solar output), and are discussed in Section 11.3.6.2. In addition, carbon cycle and other biogeochemical feedbacks in a warming climate could potentially lead to abundances of CO_2 and CH_4 (and hence RF) outside the range of the RCP scenarios, but these feedbacks are not expected to play a major role in near term climate—see Chapters 6 and 12 for further discussion.

The response of the climate system to radiative and other forcing is influenced by a very wide range of processes, not all of which are adequately simulated in the CMIP5 models (Chapter 9). Of particular concern for projections are mechanisms that could lead to major 'surprises' such as an abrupt or rapid change that affects global-to-continental scale climate. Several such mechanisms are discussed in this assessment report; these include: rapid changes in the Arctic (Section 11.3.4 and Chapter 12), rapid changes in the ocean's overturning circulation (Chapter 12), rapid change of ice sheets (Chapter 13) and rapid changes in regional monsoon systems and hydrological climate (Chapter 14). Additional mechanisms may also exist as synthesized in Chapter 12. These mechanisms have the potential to influence climate in the near term as well as in the long term, albeit the likelihood of substantial impacts increases with global warming and is generally lower for the near term. Section 11.3.6.3 provides an overall assessment of projections for global mean surface air temperature, taking into account all known quantifiable uncertainties.

11.3.6.1 Uncertainties in Future Anthropogenic Forcing and the Consequences for Near-term Climate

Climate projections for periods prior to year 2050 are not very sensitive to available alternative scenarios for anthropogenic CO_2 emissions (see Section 11.3.2.1.1; Stott and Kettleborough, 2002; Meehl et al., 2007b). Near-term projections, however, may be sensitive to changes in emissions of climate forcing agents with lifetimes shorter than CO_2, particularly the GHGs CH_4 (lifetime of a decade), tropospheric O_3 (lifetime of weeks), and tropospheric aerosols (lifetime of days). Although the RCPs and SRES scenarios span a similar range of total effective radiative forcing (ERF, see Section 7.5, Figure 7.3, Chapter 8), they include different ranges of ERF from aerosol, CH_4, and tropospheric O_3 (see Section 11.3.5.1, Tables AII.6.2 and AII.6.7 to AII.6.10). From years 2000 to 2030 the change in ERF across the RCPs ranges from –0.05 to +0.14 W m^{-2} for CH_4 and from –0.04 to +0.08 W m^{-2} for tropospheric O_3 (Tables AII.6.2 and AII.6.7; Stevenson et al., 2013). From years 2000 to 2030 the total aerosol ERF becomes less negative, increasing by +0.26 W m^{-2} for RCP8.5 (only RCP evaluated; for ACCMIP results see Table AII.6.9; Shindell et al., 2013). Total ERF change across scenarios derived from the CMIP5 ensemble can be compared only beginning in 2010. For the period 2010 to 2030, total ERF in the CMIP5 decadal averages increases by +0.5 to +1.0 W m^{-2} (RCP2.6 and RCP6.0 to RCP8.5; Table AII.6.10) while total ERF from the published RCPs increases by +0.7 to +1.1 W m^{-2} (RCP2.6 and RCP6.0 to RCP8.5, Table AII.6.8). Here we re-examine the near-term temperature increases projected from the RCPs (see Section 11.3.2.1.1) and assess the potential for changes in near-term anthropogenic forcing to induce climate responses that fall outside these scenarios.

For the different RCP pathways the increase in global mean surface temperature by 2026–2035 relative to the reference period 1986-2005 ranges from 0.74°C (RCP2.6 and RCP6.0) to 0.94°C (RCP8.5) (median of CMIP5 models, see Figure 11.24, Table AII.7.5). This inter-scenario range of 0.20°C is smaller than the inter-model spread for an individual scenario: 0.33°C to 0.52°C (defined as the 17 to 83% range of the decadal means of the models). This RCP inter-scenario spread may be too narrow as discussed in Section 11.3.5.1. The temperature increase of the most rapidly warming scenario (RCP8.5) emerges from inter-model spread (i.e., becomes greater than two times the 17 to 83% range) by about 2040, due primarily to increasing CH_4 and CO_2. By 2050 the inter-scenario spread is 0.8ºC whereas the model spread

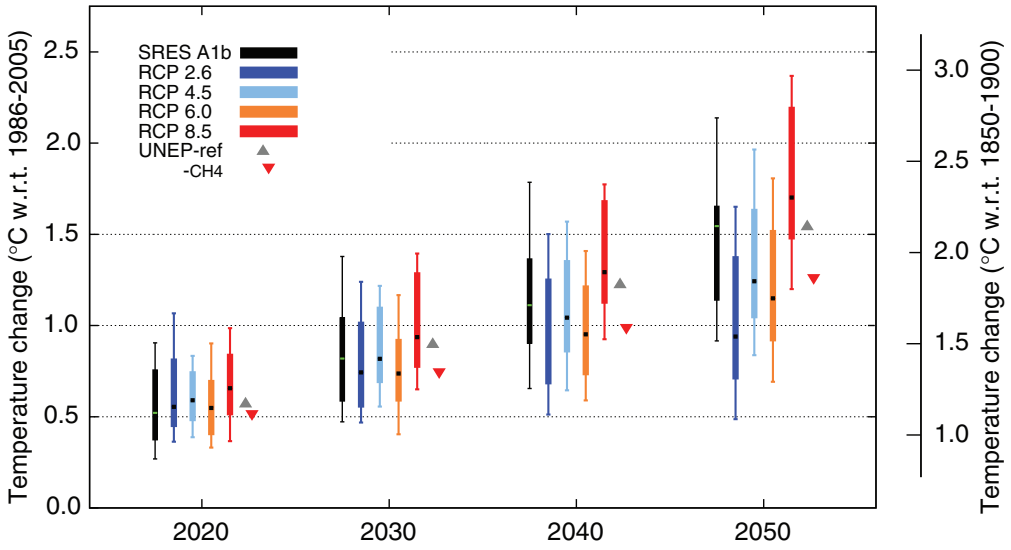

Figure 11.24a | Near-term increase in global mean surface air temperatures (°C) across scenarios. Increases in 10-year mean (2016–2025, 2026–2035, 2036–2045 and 2046–2055) relative to the reference period (1986–2005) of the globally averaged surface air temperatures. Results are shown for the CMIP5 model ensembles (see Annex I for listing of models included) for RCP2.6 (dark blue), RCP4.5 (light blue), RCP6.0 (orange), and RCP8.5 (red) and the CMIP3 model ensemble (22 models) for SRES A1b (black). The multi-model median (square), 17 to 83% range (wide boxes), 5 to 95% range (whiskers) across all models are shown for each decade and scenario. Values are provided in Table AII.7.5. Also shown are best estimates for a UNEP scenario (UNEP-ref, grey upward triangles) and one that implements technological controls on methane emissions (UNEP CH4, red downward-pointing triangles) (UNEP and WMO, 2011; Shindell et al., 2012a). Both UNEP scenarios are adjusted to reflect the 1986–2005 reference period. The right-hand floating axis shows increases in global mean surface air temperature relative to the early instrumental period (0.61°C), defined from the difference between 1850–1900 and 1986–2005 in the Hadley Centre/Climate Research Unit gridded surface temperature data set 4 (HadCRUT4) global mean temperature analysis (Chapter 2 and Table AII.1.3). Note that uncertainty remains on how to match the 1986–2005 reference period in observations with that in CMIP5 results. See discussion of Figure 11.25.

for each scenario is only 0.6ºC. At 2040 the ERF in the published RCPs ranges from 2.6 (RCP2.6) to 3.6 (RCP8.5) W m^{-2}, and about 40% of this difference is due to the steady increases in CH_4 and tropospheric O_3 found only in RCP8.5. RCP6.0 has the lowest ERF and thus warms less rapidly than other RCPs up to 2030 (Table AII.6.8).

In terms of geographic patterns of warming, differences between RCP8.5 and RCP2.6 are within ±0.5°C over most of the globe for both summer and winter seasons for 2016–2035 (Figure 11.24b), but by 2036–2055 RCP8.5 is projected to be warmer than RCP2.6 by 0.5°C to 1.0°C over most continents, and by more than 1.0°C over the Arctic in winter. Although studies suggest that the Arctic response is complex and particularly sensitive to BC aerosols (Flanner et al., 2007; Quinn et al., 2008; Jacobson, 2010; Ramana et al., 2010; Bond et al., 2013; Sand et al., 2013), the difference in ERF between RCP2.6 and RCP8.5 is dominated by the GHGs, as the BC atmospheric burden is decreasing through the century with little difference across the RCPs (Table AII.5.7).

Large changes in emissions of the well-mixed greenhouse gases (WMGHGs) produce only modest changes in the near term because these gases are long lived: For example, a 50% cut in Kyoto-gas emissions beginning in 1990 offsets the warming that otherwise would have occurred by only –0.11°C ± 0.03°C after 12 years (Prather et al., 2009). In contrast, many studies have noted the large potential for air pollutant emission reductions to influence near-term climate because RF from these species responds almost immediately to changes in emissions. Decreases in sulphate aerosol have occurred through mitigation of both air pollution and fossil-fuel emissions, and are expected to produce a near-term rise in surface temperatures (e.g., Jacobson and Streets, 2009; Raes and Seinfeld, 2009; Wigley et al., 2009; Kloster et al., 2010; Makkonen et al., 2012).

Because global mean aerosol forcing decreases in all RCP scenarios (AII.5.3 to AII.5.7, AII.6.9; see Section 11.3.5), the potential exists for a systematic difference between the CMIP3 models forced with the SRES scenarios and the CMIP5 models forced with the RCP scenarios. One study directly addressed the impacts of aerosols on climate under the RCP4.5 scenario, and found that the aerosol emission reductions induce about a 0.2°C warming in the near term compared with fixed 2005 aerosol levels (more indicative of the SRES CMIP3 aerosols) (Levy et al., 2013). The cooling over the period 1951–2010 that is attributed to non-WMGHG anthropogenic forcing in the CMIP5 models (Figures 10.4 and 10.5) has a *likely* range of –0.25°C ± 0.35°C compared to +0.9°C ± 0.4°C for WMGHG. The non-WMGHG forcing generally includes the influence of non-aerosol warming agents over the historical period such as tropospheric ozone, and a simple correction would give an aerosol-only cooling that is about 50% larger in magnitude (see ERF components, Chapter 8). The near-term reductions in total aerosol emissions, however, even under the MFR scenario, are at most about 50% (AII.2.17 to AII.2.22), indicating a maximum near-term temperature response of about half that induced by the addition of aerosols over the last century. Hence, the evidence indicates that differences in aerosol loading from the SRES (conservatively assuming roughly constant aerosols) to the RCP scenarios can increase warming in the CMIP5 models relative to the CMIP3 models by up to 0.2°C in the near term for the same WMGHG forcing (*medium confidence*).

Many studies show that air pollutants influence climate and identify approaches to mitigate both air pollution and global warming by

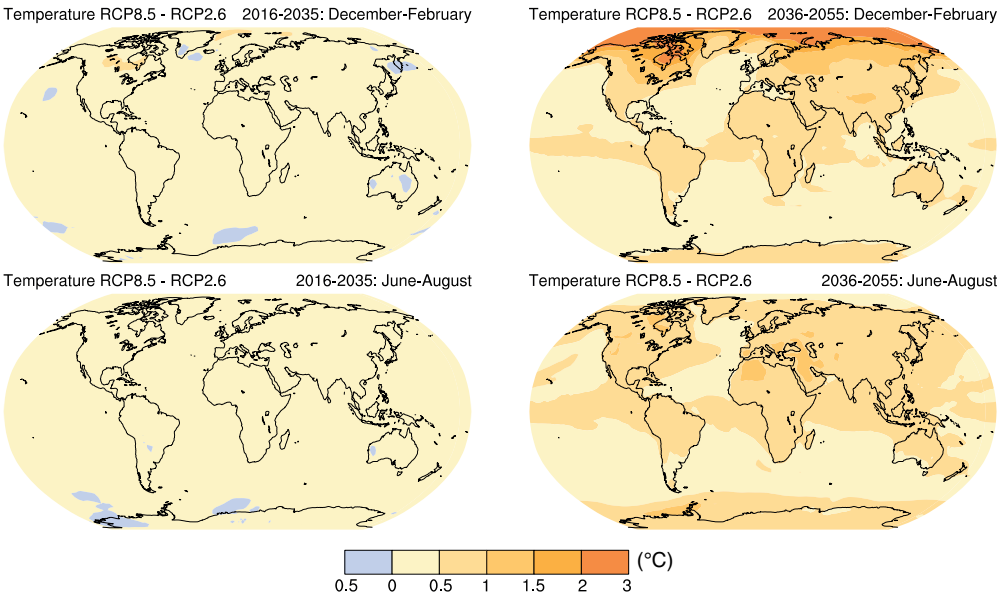

Figure 11.24b | Global maps of near-term differences in surface air temperature across the RCP scenarios. Differences between (RCP8.5) and low (RCP2.6) scenarios for the CMIP5 model ensemble (31 models) are shown for averages over 2016–2035 (left) and 2036–2055 (right) in boreal winter (December, January and February; top row) and summer (June, July and August; bottom row).

decreasing CH_4, tropospheric O_3 and absorbing aerosols, particularly BC (e.g., Hansen et al., 2000; Fiore et al., 2002, 2008, 2009; Dentener et al., 2005; West et al., 2006; Royal Society, 2008; Jacobson, 2010; Penner et al., 2010; UNEP and WMO, 2011; Anenberg et al., 2012; Shindell et al., 2012b; Unger, 2012; Bond et al., 2013). An alternative set of technologically based scenarios (UNEP and WMO, 2011) that examined controls on CH_4 and BC emissions designed to reduce tropospheric CH_4, O_3 and BC also included reductions of co-emitted species (e.g., CO, OC, NO_x). These reductions were applied in two CMIP5 models, and then those model responses were combined with the AR4 best estimates for the range of climate sensitivity and for uncertainty estimates for each component of RF (Shindell et al., 2012a). This approach provided a near-term best estimate and range of global mean temperature change for the reference (UNEP-ref) and CH_4-mitigation (UNEP-CH4) scenarios (Figure 11.24a, adjusted to reflect the 1986–2005 reference period). Under UNEP-CH4, anthropogenic CH_4 emissions decrease by 24% from 2010 to 2030, and global warming is reduced by 0.16°C (best estimate) at 2030 and by 0.28°C at 2050. A third UNEP scenario (UNEP-BC+CH4; not shown) adds reductions in BC by 78% onto CH_4 mitigation and reduces warming by an additional 0.12°C (best estimate) at 2030. However, it greatly increases the uncertainty owing to poor understanding of associated cloud adjustments (i.e., semi-direct and indirect effects) as well as of the ratio of BC to co-emitted reflective OC aerosols, their size distributions and mixing states (see Chapter 7, Section 7.5). Corresponding BC reductions in the RCPs are only 4 to 11%.

Beyond global mean temperature, shifting magnitudes and geographic patterns of emissions may induce aerosol-specific changes in regional atmospheric circulation and precipitation. See Chapter 7, especially Sections 7.6.2 and 7.6.4, for assessment of this work (Roeckner et al., 2006; Menon and et al., 2008; Ming et al., 2010, 2011; Ott et al., 2010; Randles and Ramaswamy, 2010; Allen and Sherwood, 2011; Bollasina et al., 2011; Leibensperger et al., 2011b;Fyfe et al., 2012; Ganguly et al., 2012; Rotstayn et al., 2012; Shindell et al., 2012b; Teng et al., 2012; Bond et al., 2013). Recent trends in aerosol–fog interactions and snowpack decline are implicated in more rapid regional warming in Europe (van Oldenborgh et al., 2010; Ceppi et al., 2012; Scherrer et al., 2012), and coupling of aerosols and soil moisture could increase near-term local warming in the eastern USA (Mickley et al., 2011). Major changes in the tropical circulation and rainfall have been attributed to increasing aerosols, but studies often disagree in sign (see Section 11.3.2.4.3, Chapters 10 and 14). The lack of standardization (e.g., different regions, different mixtures of reflecting and absorbing aerosols) and agreement across studies prevents generalization of these findings to project aerosol-induced changes in regional atmospheric circulation or precipitation in the near term.

Land use and land cover change (LULCC; see Chapter 6), including deforestation, forest degradation and agricultural expansion for bioenergy (Georgescu et al., 2009; Anderson-Teixeira et al., 2012), can alter global climate forcing through changing surface albedo (assessed as ERF; Chapter 8), the hydrological cycle, GHGs (for CO_2, see Chapters 6 and 12), or aerosols. The shift from forest to grassland in many places since the pre-industrial era has been formally attributed as a cause of regionally lower mean and extreme temperatures (Christidis et al., 2013). RCP CO_2 and CH_4 anthropogenic emissions include land use changes (Hurtt et al., 2011) that vary with the underlying storylines and differ across RCPs. These global-scale changes in crop and pasture land projected over the near term (+2% for RCP2.6 and RCP8.5; –4% for RCP4.5and RCP6.0) are smaller in magnitude than the 1950–2000 change (+6%) (see Figure 6.23). Overall LULCC has had small impact on ERF (–0.15 W m^{-2}; see AII.1.2) and thus as projected is not a major factor in near-term climate change on global scales.

Land use changes can also lead to sustained near-term changes in regional climate through modification of the biogeophysical proper-

ties that alter the water and energy cycles. Local- and regional-scale climate responses to LULCC can exceed those associated with global mean warming (Baidya Roy and Avissar, 2002; Findell et al., 2007; Pitman et al., 2009, 2012; Pielke et al., 2011; Boisier et al., 2012; de Noblet-Ducoudre et al., 2012; Lee and Berbery, 2012). Examples of LULCC-driven changes include: Brazilian conversion to sugarcane induces seasonal shifts of 1 to 2°C (Georgescu et al., 2013); European forested areas experience less severe heat waves (Teuling et al., 2010); and deforested regions over the Amazon lack deep convective clouds (Wang et al., 2009). Systematic assessment of near-term, local-to-regional climate change is beyond the scope here.

In summary, climate projections for the near term are not very sensitive to the range in anthropogenic emissions of CO_2 and other WMGHGs. By the 2040s the CMIP5 median for global mean temperature ranges from a low of +0.9°C (RCP2.6 and RCP6.0) to a high of +1.3°C (RCP8.5) above the CMIP5 reference period (Figure 11.24a; Table AII.7.5). See discussion below regarding possible offsets between the observed and CMIP5 reference periods. Alternative CH_4 scenarios incorporating large emission reductions outside the RCP range would offset near-term warming by –0.2°C (*medium confidence*). Aerosols remain a major source of uncertainty in near-term projections, on both global and regional scales. Removal of half of the sulphate aerosol, as projected before 2030 in the MFR scenario and by 2050 in most RCPs, would increase warming by up to +0.2°C (*medium confidence*). Actions to reduce BC aerosol could reduce warming, but the magnitude is highly uncertain, depending on co-emitted (reflective) aerosols and aerosol-cloud interactions (Chapter 7; Section 7.5). In addition, near-term climate change, including extremes and precipitation, may be driven locally by land use change and shifting geographic patterns of aerosols; and these regional climatic effects may exceed those induced by the global ERF.

11.3.6.2 Uncertainties in Future Natural Radiative Forcing and the Consequences for Near-term Climate

11.3.6.2.1 The effects of future volcanic eruptions

As discussed in Chapters 8 and 10, explosive volcanic eruptions are the major cause of natural variations in RF on interannual to decadal time scales. Most important are large tropical and subtropical eruptions that inject substantial amounts of SO_2 directly into the stratosphere. The subsequent formation of sulphate aerosols leads to a negative RF of several watts per metre squared, with a typical lifetime of a year (Robock, 2000). The eruption of Mt Pinatubo in 1991 was one of the largest in recent times, with a return period of about three times per century, but dwarfed by Tambora in 1815 (Gao et al., 2008). Mt Pinatubo caused a rapid drop in a global mean surface air temperature of several tenths of a degree Celsius over the following year, but this signal disappeared over the next five years (Hansen et al., 1992; Soden et al., 2002; Bender et al., 2010). In addition to global mean cooling, there are effects on the hydrological cycle (e.g., Trenberth and Dai, 2007), atmosphere and ocean circulation (e.g., Stenchikov et al., 2006; Ottera et al., 2010). The surface climate response typically persists for a few years, but the subsurface ocean response can persist for decades or centuries, with consequences for sea level rise (Delworth et al., 2005; Stenchikov et al., 2009; Gregory, 2010; Timmreck, 2012).

Although it is possible to detect when various existing volcanoes become more active, or are more likely to erupt, the precise timing of an eruption, the amount of SO_2 emitted and its distribution in the stratosphere are not predictable until after the eruption. Eruptions comparable to Mt Pinatubo can be expected to cause a short-term cooling of the climate with related effects on surface climate that persist for a few years before a return to warming trajectories discussed in Section 11.3.2. Larger eruptions, or several eruptions occurring close together in time, would lead to larger and/or more persistent effects.

11.3.6.2.2 The effects of future changes in solar forcing

Some of the future CMIP5 climate simulations using the RCP scenarios include an 11-year variation in total solar irradiance (TSI) but no underlying trend beyond 2005. Chapter 10 noted that there has been little observed trend in TSI during a time period of rapid global warming since the late 1970s, but that the 11-year solar cycle does introduce a significant and measurable pattern of response in the troposphere (Section 10.3.1.1.3). As discussed in Chapter 8 (Section 8.4.1.3), the Sun has been in a 'grand solar maximum' of magnetic activity on the multi-decadal time scale. However, the most recent solar minimum was the lowest and longest since 1920, and some studies (e.g., Lockwood, 2010) suggest there could be a continued decline towards a much quieter period in the coming decades, but there is *low confidence* in these projections (Section 8.4.1.3). Nevertheless, if there is such a reduction in solar activity, there is *high confidence* that the variations in TSI RF will be much smaller than the projected increased forcing due to GHGs (Section 8.4.1.3). In addition, studies that have investigated the effect of a possible decline in TSI on future climate have shown that the associated decrease in global mean surface temperature is much smaller than the warming expected from increases in anthropogenic GHGs (Feulner and Rahmstorf, 2010; Jones et al., 2012; Meehl et al., 2013b) However, regional impacts could be more significant (Xoplaki et al., 2001; Mann et al., 2009; Gray et al., 2010; Ineson et al., 2011).

As discussed in Section 8.4.1, a recent satellite measurement (Harder et al., 2009) found much greater than expected reduction at ultraviolet (UV) wavelengths in the recent declining solar cycle phase. Changes in solar UV drive stratospheric O_3 chemistry and can change RF. Haigh et al. (2010) show that if these observations are correct, they imply the opposite relationship between solar RF and solar activity over that period than has hitherto been assumed. These new measurements therefore increase uncertainty in estimates of the sign of solar RF, but they are not expected to alter estimates of the maximum absolute magnitude of the solar contribution to RF, which remains small (Chapter 8). However, they do suggest the possibility of a much larger impact of solar variations on the stratosphere than previously thought, and some studies have suggested that this may lead to significant regional impacts on climate (as discussed in Section 10.3.1.1.3) that are not necessarily reflected by the RF metric (see Section 8.4.1).

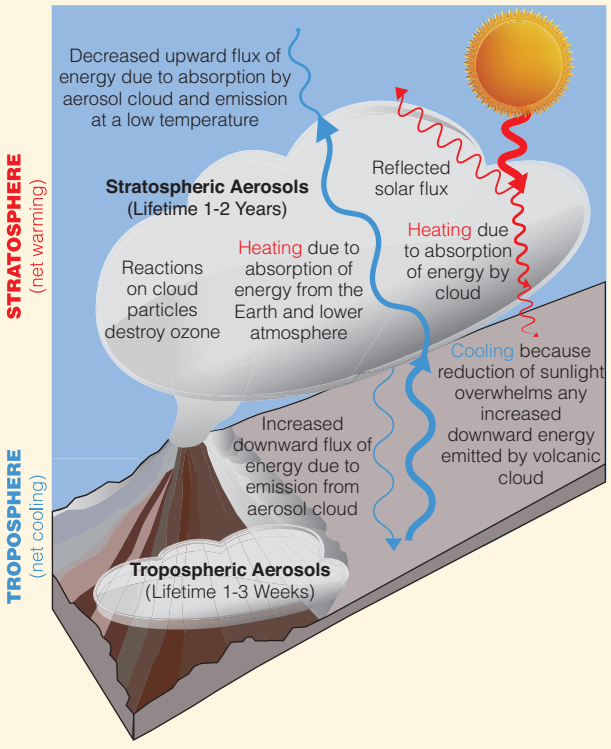
In summary, possible future changes in solar irradiance could influence the rate at which global mean surface air temperature increases, but there is *high confidence* that this influence will be small in comparison to the influence of increasing concentrations of GHGs in the atmosphere. Understanding of the impacts of changes in solar irradiance on continental and sub-continental scale climate remains low.

Frequently Asked Questions

FAQ 11.2 | How Do Volcanic Eruptions Affect Climate and Our Ability to Predict Climate?

Large volcanic eruptions affect the climate by injecting sulphur dioxide gas into the upper atmosphere (also called stratosphere), which reacts with water to form clouds of sulphuric acid droplets. These clouds reflect sunlight back to space, preventing its energy from reaching the Earth's surface, thus cooling it, along with the lower atmosphere. These upper atmospheric sulphuric acid clouds also locally absorb energy from the Sun, the Earth and the lower atmosphere, which heats the upper atmosphere (see FAQ 11.2, Figure 1). In terms of surface cooling, the 1991 Mt Pinatubo eruption in the Philippines, for example, injected about 20 million tons of sulphur dioxide (SO_2) into the stratosphere, cooling the Earth by about 0.5°C for up to a year. Globally, eruptions also reduce precipitation, because the reduced incoming shortwave at the surface is compensated by a reduction in latent heating (i.e., in evaporation and hence rainfall).

For the purposes of predicting climate, an eruption causing significant global surface cooling and upper atmospheric heating for the next year or so can be expected. The problem is that, while a volcano that has become more active can be detected, the precise timing of an eruption, or the amount of SO_2 injected into the upper atmosphere and how it might disperse cannot be predicted. This is a source of uncertainty in climate predictions.



Large volcanic eruptions produce lots of particles, called ash or tephra. However, these particles fall out of the atmosphere quickly, within days or weeks, so they do not affect the global climate. For example, the 1980 Mount St. Helens eruption affected surface temperatures in the northwest USA for several days but, because it emitted little SO_2 into the stratosphere, it had no detectable global climate impacts. If large, high-latitude eruptions inject sulphur into the stratosphere, they will have an effect only in the hemisphere where they erupted, and the effects will only last a year at most, as the stratospheric cloud they produce only has a lifetime of a few months.

Tropical or subtropical volcanoes produce more global surface or tropospheric cooling. This is because the resulting sulphuric acid cloud in the upper atmosphere lasts between one and two years, and can cover much of the globe. However, their regional climatic impacts are difficult to predict, because dispersion of stratospheric sulphate aerosols depends heavily on atmospheric wind conditions at the time of eruption. Furthermore, the surface cooling effect is typically not uniform: because continents cool more than the ocean, the summer monsoon can weaken, reducing rain over Asia and Africa. The climatic response is complicated further by the fact that upper atmospheric clouds from tropical eruptions also absorb sunlight and heat from the Earth, which produces more upper atmosphere warming in the tropics than at high latitudes.

The largest volcanic eruptions of the past 250 years stimulated scientific study. After the 1783 Laki eruption in Iceland, there were record warm summer temperatures in Europe, followed by a very cold winter. Two large eruptions, an unidentified one in 1809, and the 1815 Tambora eruption caused the 'Year Without a Summer' in 1816. Agricultural failures in Europe and the USA that year led to food shortages, famine and riots.

The largest eruption in more than 50 years, that of Agung in 1963, led to many modern studies, including observations and climate model calculations. Two subsequent large eruptions, El Chichón in 1982 and Pinatubo in 1991, inspired the work that led to our current understanding of the effects of volcanic eruptions on climate.

(continued on next page)

FAQ 11.2, Figure 1 | Schematic of how large tropical or sub-tropical volcanoes impact upper atmospheric (stratospheric) and lower atmospheric (tropospheric) temperatures.

FAQ 11.2 (continued)

Volcanic clouds remain in the stratosphere only for a couple of years, so their impact on climate is correspondingly short. But the impacts of consecutive large eruptions can last longer: for example, at the end of the 13th century there were four large eruptions—one every ten years. The first, in 1258 CE, was the largest in 1000 years. That sequence of eruptions cooled the North Atlantic Ocean and Arctic sea ice. Another period of interest is the three large, and several lesser, volcanic events during 1963–1991 (see Chapter 8 for how these eruptions affected atmospheric composition and reduced shortwave radiation at the ground.

Volcanologists can detect when a volcano becomes more active, but they cannot predict whether it will erupt, or if it does, how much sulphur it might inject into the stratosphere. Nevertheless, volcanoes affect the ability to predict climate in three distinct ways. First, if a violent eruption injects significant volumes of sulphur dioxide into the stratosphere, this effect can be included in climate predictions. There are substantial challenges and sources of uncertainty involved, such as collecting good observations of the volcanic cloud, and calculating how it will move and change during its lifetime. But, based on observations, and successful modelling of recent eruptions, some of the effects of large eruptions can be included in predictions.

The second effect is that volcanic eruptions are a potential source of uncertainty in our predictions. Eruptions cannot be predicted in advance, but they will occur, causing short-term climatic impacts on both local and global scales. In principle, this potential uncertainty can be accounted for by including random eruptions, or eruptions based on some scenario in our near-term ensemble climate predictions. This area of research needs further exploration. The future projections in this report do not include future volcanic eruptions.

Third, the historical climate record can be used, along with estimates of observed sulphate aerosols, to test the fidelity of our climate simulations. While the climatic response to explosive volcanic eruptions is a useful analogue for some other climatic forcings, there are limitations. For example, successfully simulating the impact of one eruption can help validate models used for seasonal and interannual predictions. But in this way not all the mechanisms involved in global warming over the next century can be validated, because these involve long term oceanic feedbacks, which have a longer time scale than the response to individual volcanic eruptions.

11.3.6.3 Synthesis of Near-term Projections of Global Mean Surface Air Temperature

Figure 11.25 provides a synthesis of near-term projections of global mean surface air temperature (GMST) from CMIP5, CMIP3 and studies that have attempted to use observations to quantify projection uncertainty (see Section 11.3.2.1). On the basis of this evidence, an attempt is made here to assess a *likely* range for GMST in the period 2016–2035. Such an overall assessment is not straightforward. The following points must be taken into account:

1. No likelihoods are associated with the different RCP scenarios. For this reason, previous IPCC Assessment Reports have only presented projections that are conditional on specific scenarios. Here we attempt a broader assessment across all four RCP scenarios. This is possible only because, as discussed in Section 11.3.6.1, *near-term* projections of GMST are not especially sensitive to these different scenarios.

2. In the near term it is expected that increases in GMST will be driven by past and future increases in GHG concentrations and future decreases in anthropogenic aerosols, as found in all the RCP scenarios. Figure 11.25c shows that in the near term the CMIP3 projections based on the SRES scenarios are generally cooler than the CMIP5 projections based on the RCP scenarios. This difference is at least partly attributable to higher aerosol concentrations in the SRES scenarios (see Section 11.3.6.1).

3. The CMIP3 and CMIP5 projections are ensembles of opportunity, and it is explicitly recognized that there are sources of uncertainty not simulated by the models. Evidence of this can be seen by comparing the Rowlands et al. (2012) projections for the A1B scenario, which were obtained using a very large ensemble in which the physics parameterizations were perturbed in a single climate model, with the corresponding raw multi-model CMIP3 projections. The former exhibit a substantially larger *likely* range than the latter. A pragmatic approach to addressing this issue, which was used in the AR4 and is also used in Chapter 12, is to consider the 5 to 95% CMIP3/5 range as a '*likely*' rather than '*very likely*' range.

4. As discussed in Section 11.3.6.2, the RCP scenarios assume no underlying trend in total solar irradiance and no future volcanic eruptions. Future volcanic eruptions cannot be predicted and there is *low confidence* in projected changes in solar irradiance (Chapter 8). Consequently the possible effects of future changes in natural forcings are excluded from the assessment here.

5. As discussed in Section 11.3.2.1.1 observationally constrained 'ASK' projections (Gillett et al., 2013; Stott et al., 2013) are 10 to 15% cooler (median values for RCP4.5; 6–10% cooler for RCP8.5), and have a narrower range, than the corresponding 'raw' (uninitialized) CMIP5 projections. The reduced rate of warming in the ASK projections is related to evidence from Chapter 10 (Section 10.3.1) that 'some CMIP5 models have a higher transient response to GHGs and a larger response to other anthropogenic forcings (dominated by the effects of aerosols) than the real world (*medium confidence*).' These models may warm too rapidly as GHGs increase and aerosols decline.

6. Over the last two decades the observed rate of increase in GMST has been at the lower end of rates simulated by CMIP5 models (Figure 11.25a). This hiatus in GMST rise is discussed in detail in Box 9.2 (Chapter 9), where it is concluded that the hiatus is attributable, in roughly equal measure, to a decline in the rate of increase in ERF and a cooling contribution from internal variability (expert judgment, *medium confidence*). The decline in the rate of increase in ERF is attributed primarily to natural (solar and volcanic) forcing but there is *low confidence* in quantifying the role of forcing trend in causing the hiatus, because of uncertainty in the magnitude of the volcanic forcing trend and *low confidence* in the aerosol forcing trend. Concerning the higher rate of warming in CMIP5 simulations it is concluded that there is a substantial contribution from internal variability but that errors in ERF and in model responses may also contribute. There is *low confidence* in this assessment because of uncertainties in aerosol forcing in particular.

   The observed hiatus has important implications for near-term projections of GMST. A basic issue concerns the sensitivity of projections to the choice of reference period. Figure 11.25b and c shows the 5 to 95% ranges for CMIP5 projections using a 1986–2005 reference period (light grey), and the same projections using a 2006–2012 reference period (dark grey). The latter projections are cooler, and the effect of using a more recent reference period appears similar to the effect of initialization (discussed in Section 11.3.2.1.1 and shown in Figure 11.25c for RCP4.5). Using this more recent reference period, the 5 to 95% range for the mean GMST in 2016–2035 relative to 1986–2005 is 0.36°C to 0.79°C (using all RCP scenarios, weighted to ensure equal weights per model and using an estimate of the observed GMST anomaly for (2006–2012)–(1986–2005) of 0.16°C). This range may be compared with the range of 0.48°C to 1.15°C obtained from the CMIP5 models using the original 1986–2005 reference period.

7. In view of the sensitivity of projections to the reference period it is helpful to consider the possible rate of change of GMST in the near term. The CMIP5 5 to 95% ranges for GMST trends in the period 2012–2035 are 0.11°C to 0.41°C per decade. This range is similar to, though slightly narrower than, the range found by Easterling and Wehner (2009) for the CMIP3 SRES A2 scenario over the longer period 2000–2050. It may also be compared with recent rates in the observational record (e.g., ~0.26°C per decade for 1984–1998 and ~0.04°C per decade for hiatus period 1998–2012; See Box 9.2). The RCP scenarios project that ERF will increase more rapidly in the near term than occurred over the hiatus period (see Box 9.2 and Annex II), which is consistent with more rapid warming. In addition, Box 9.2 includes an assessment that internal variability is *more likely than not* to make a positive contribution to the increase in GMST in the near term. Internal variability is included in the CMIP5 projections, but because most of the CMIP5 simulations do not reproduce the observed reduction in global mean surface warming over the last 10 to 15 years, the distribution of CMIP5 near-term trends will not reflect this assessment and might, as a result, be biased low. This uncertainty, however, is somewhat counter balanced by the evidence of point 5, which suggests a high bias in the distribution of near-term trends. A further projection of GMST for the period 2016–2035 may be obtained by starting from the observed GMST for 2012 (0.14°C relative to 1986–2005) and projecting increases at rates between the 5 to 95% CMIP5 range of 0.11°C to 0.41°C per decade. The resulting range of 0.29°C to 0.69°C, relative to 1986–2005, is shown on Figure 11.25(c).

Overall, in the absence of major volcanic eruptions—which would cause significant but temporary cooling—and, assuming no significant future long term changes in solar irradiance, it is *likely* (>66% probability) that the GMST anomaly for the period 2016–2035, relative to the reference period of 1986–2005 will be in the range 0.3°C to 0.7°C (expert assessment, to one significant figure; *medium confidence*). This range is consistent, to one significant figure, with the range obtained by using CMIP5 5 to 95% model trends for 2012–2035. It is also consistent with the CMIP5 5 to 95% range for all four RCP scenarios of 0.36°C to 0.79°C, using the 2006–2012 reference period, after the upper and lower bounds are reduced by 10% to take into account the evidence noted under point 5 that some models may be too sensitive to anthropogenic forcing. The 0.3°C to 0.7°C range includes the *likely* range of the ASK projections and initialized predictions for RCP4.5. It corresponds to a rate of change of GMST between 2012 and 2035 in the range 0.12°C to 0.42°C per decade. The higher rates of change can be associated with a significant positive contribution from internal variability (Box 9.2) and/or high rates of increase in ERF (e.g., as found in RCP8.5). Note that an upper limit of 0.8°C on the 2016–2035 GMST corresponds to a rate of change over the period 2012–2035 of 0.49°C per decade, which is considered *unlikely*. The assessed rates of change are consistent with the AR4 SPM statement that 'For the next two decades, a warming of about 0.2°C per decade is projected for a range of SRES emission scenarios'. However, the implied rates of warming over the period from 1986–2005 to 2016–2035 are lower as a result of the hiatus: 0.10°C to 0.23°C per decade, suggesting the AR4 assessment was near the upper end of current expectations for this specific time interval.

The assessment here provides only a *likely* range for GMST. Possible reasons why the real world might depart from this range include: RF departs significantly from the RCP scenarios, due to either natural (e.g., major volcanic eruptions, changes in solar irradiance) or anthropogenic (e.g., aerosol or GHG emissions) causes; processes that are poorly simulated in the CMIP5 models exert a significant influence on GMST. The latter class includes: a possible strong 'recovery' from the recent hiatus in GMST; the possibility that models might underestimate decadal variability (but see Section 9.5.3.1); the possibility that model sensitivity to anthropogenic forcing may differ from that of the real world (see point

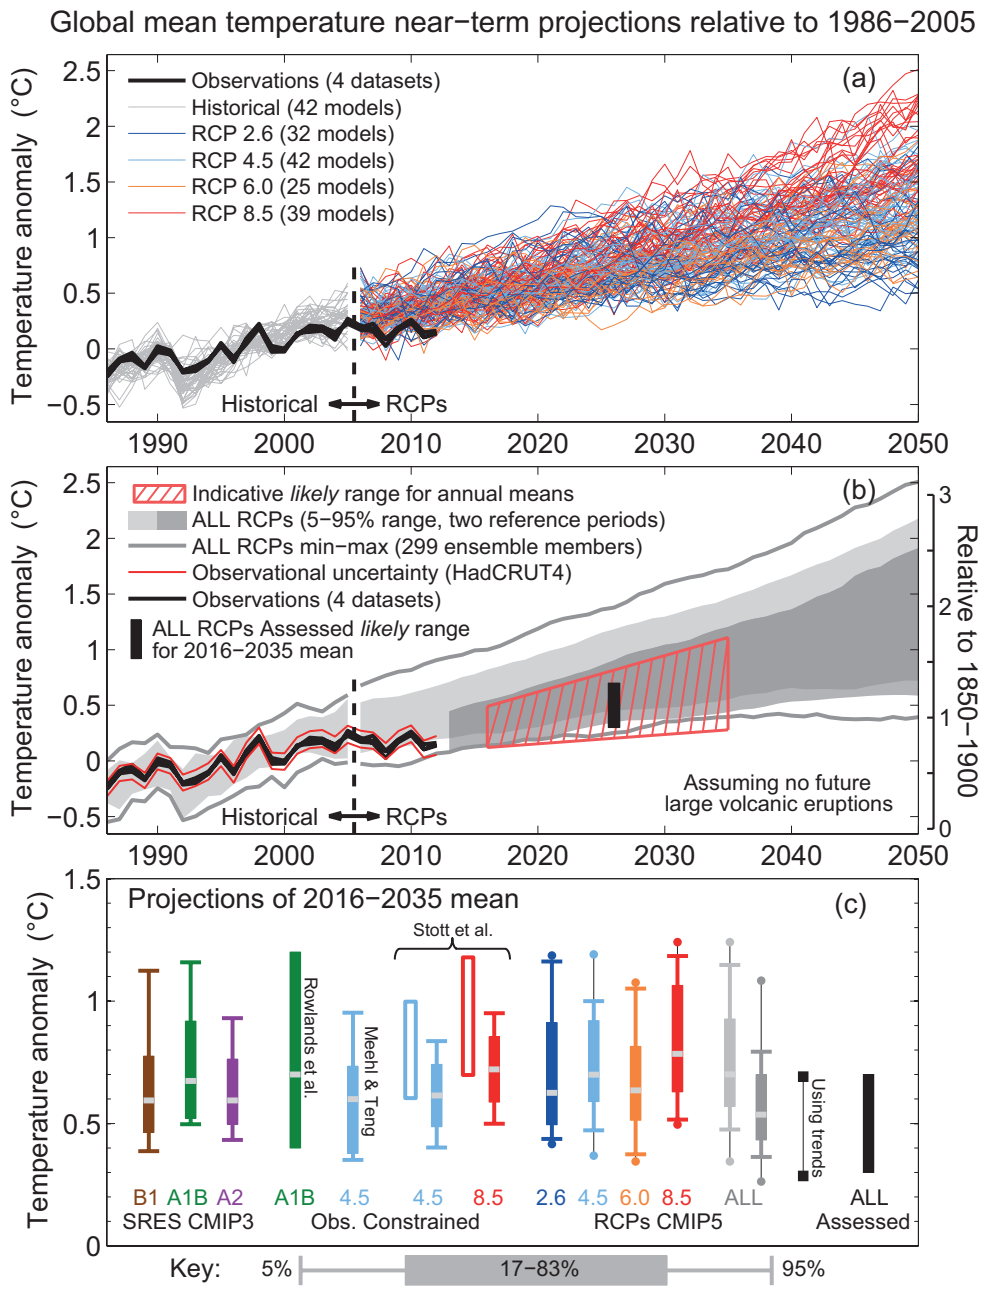


Figure 11.25 | Synthesis of near-term projections of global mean surface air temperature (GMST). (a) Simulations and projections of annual mean GMST 1986–2050 (anomalies relative to 1986–2005). Projections under all RCPs from CMIP5 models (grey and coloured lines, one ensemble member per model), with four observational estimates (Hadley Centre/Climate Research Unit gridded surface temperature data set 4 (HadCRUT4): Morice et al., 2012); European Centre for Medium range Weather Forecast (ECMWF) interim reanalysis of the global atmosphere and surface conditions (ERA-Interim): Simmons et al., 2010); Goddard Institute of Space Studies Surface Temperature Analysis (GISTEMP): Hansen et al., 2010); National Oceanic and Atmospheric Administration (NOAA): Smith et al., 2008)) for the period 1986–2012 (black lines). (b) As (a) but showing the 5 to 95% range of annual mean CMIP5 projections (using one ensemble member per model) for all RCPs using a reference period of 1986–2005 (light grey shade) and all RCPs using a reference period of 2006–2012, together with the observed anomaly for (2006–2012) to (1986–2005) of 0.16°C (dark grey shade). The percentiles for 2006 onwards have been smoothed with a 5-year running mean for clarity. The maximum and minimum values from CMIP5 using all ensemble members and the 1986–2005 reference period are shown by the grey lines (also smoothed). Black lines show annual mean observational estimates. The red hatched region shows the indicative *likely* range for annual mean GMST during the period 2016–2035 based on the 'ALL RCPs Assessed' *likely* range for the 20-year mean GMST anomaly for 2016–2035, which is shown as a black bar in both (b) and (c) (see text for details). The temperature scale on the right hand side shows changes relative to a reference period of 1850-1900, assuming a warming of GMST between 1850-1900 and 1986-2005 of 0.61°C estimated from HadCRUT4.The temperature scale relative to the 1850-1900 period on the right-hand side assumes a warming of GMST prior to 1986–2005 of 0.61°C estimated from HadCRUT4. (c) A synthesis of projections for the mean GMST anomaly for 2016–2035 relative to 1986–2005. The box and whiskers represent the 66% and 90% ranges. Shown are unconstrained SRES CMIP3 and RCP CMIP5 projections; observationally constrained projections: Rowlands et al. (2012) for SRES A1B scenario, updated to remove simulations with large future volcanic eruptions; Meehl and Teng (2012) for RCP4.5 scenario, updated to include 14 CMIP5 models; Stott et al. (2013), based on six CMIP5 models with unconstrained 66% ranges for these six models shown as unfilled boxes; unconstrained projections for all four RCP scenarios using two reference periods as in panel b (light grey and dark grey shades, consistent with panel b); 90% range estimated using CMIP5 trends for the period 2012–2035 and the observed GMST anomaly for 2012; an overall *likely* (>66%) assessed range for all RCP scenarios. The dots for the CMIP5 estimates show the maximum and minimum values using all ensemble members. The medians (or maximum likelihood estimate for Rowlands et al. 2012) are indicated by a grey band.

Table 11.3 | Percentage of CMIP5 models for which the projected change in global mean surface air temperature, relative to 1850-1900, crosses the specified temperature levels, by the specified time periods and assuming the specified RCP scenarios. The projected temperature change relative to the mean temperature in the period 1850-1900 is calculated using the models' projected temperature change relative to 1986–2005 plus the observed temperature change between 1850–1900 and 1986–2005 of 0.61°C estimated from the Hadley Centre/Climate Research Unit gridded surface temperature data set 4 (HadCRUT4; Morice et al., 2012). The percentages in brackets use an alternative reference period for the model projections of 2006–2012, together with the observed temperature difference between 1986–2005 and 2006–2012 of 0.16°C. The definition of crossing is that the 20-year mean exceeds the specified temperature level. Note that these percentages should *not* be interpreted as likelihoods because there are other sources of uncertainty (see discussion in Section 11.3.6.3).

Scenario	Early (2016–2035)	Mid (2046–2065)
Temperature +1.0°C		
RCP 2.6	100% (84%)	100% (94%)
RCP 4.5	98% (93%)	100% (100%)
RCP 6.0	96% (80%)	100% (100%)
RCP 8.5	100% (100%)	100% (100%)
Temperature +1.5°C		
RCP 2.6	22% (0%)	56% (28%)
RCP 4.5	17% (0%)	95% (86%)
RCP 6.0	12% (0%)	92% (88%)
RCP 8.5	33% (5%)	100% (100%)
Temperature +2.0°C		
RCP 2.6	0% (0%)	16% (3%)
RCP 4.5	0% (0%)	43% (29%)
RCP 6.0	0% (0%)	32% (20%)
RCP 8.5	0% (0%)	95% (90%)
Temperature +3.0°C		
RCP 2.6	0% (0%)	0% (0%)
RCP 4.5	0% (0%)	0% (0%)
RCP 6.0	0% (0%)	0% (0%)
RCP 8.5	0% (0%)	21% (5%)

5); and the possibility of abrupt changes in climate (see introduction to Sections 11.3.6 and 12.5.5).

The assessment here has focused on 20-year mean values of GMST for the period 2016–2035. There is no unique method to derive a *likely* range for annual mean values from the range for 20-year means, so such calculations necessarily involve additional uncertainties (beyond those outlined in the previous paragraph), and lower confidence. Nevertheless, it is useful to attempt to estimate a range for annual mean values, which may be compared with raw model projections and, in the future, with observations. To do so, the following simple approach is used: (1) Starting in 2009 from the observed GMST anomaly for 2006–2012 of 0.16°C (relative to 1986–2005), linear trends are projected over the period 2009–2035 with maximum and minimum gradients selected to be consistent with the 0.3°C to 0.7°C range for the mean GMST in the period 2016–2035; 2). To take into account the expected year-to-year variability of annual mean values, the resulting linear trends are offset by ±0.1°C. The value of 0.1°C is based on the standard deviation of annual means in CMIP5 control runs (to one significant figure). These calculations provide an indicative *likely* range for annual mean GMST, which is shown as the red hatched area in Figure 11.25b. Note that this range does not take into account the expected impact of any future volcanic eruptions.

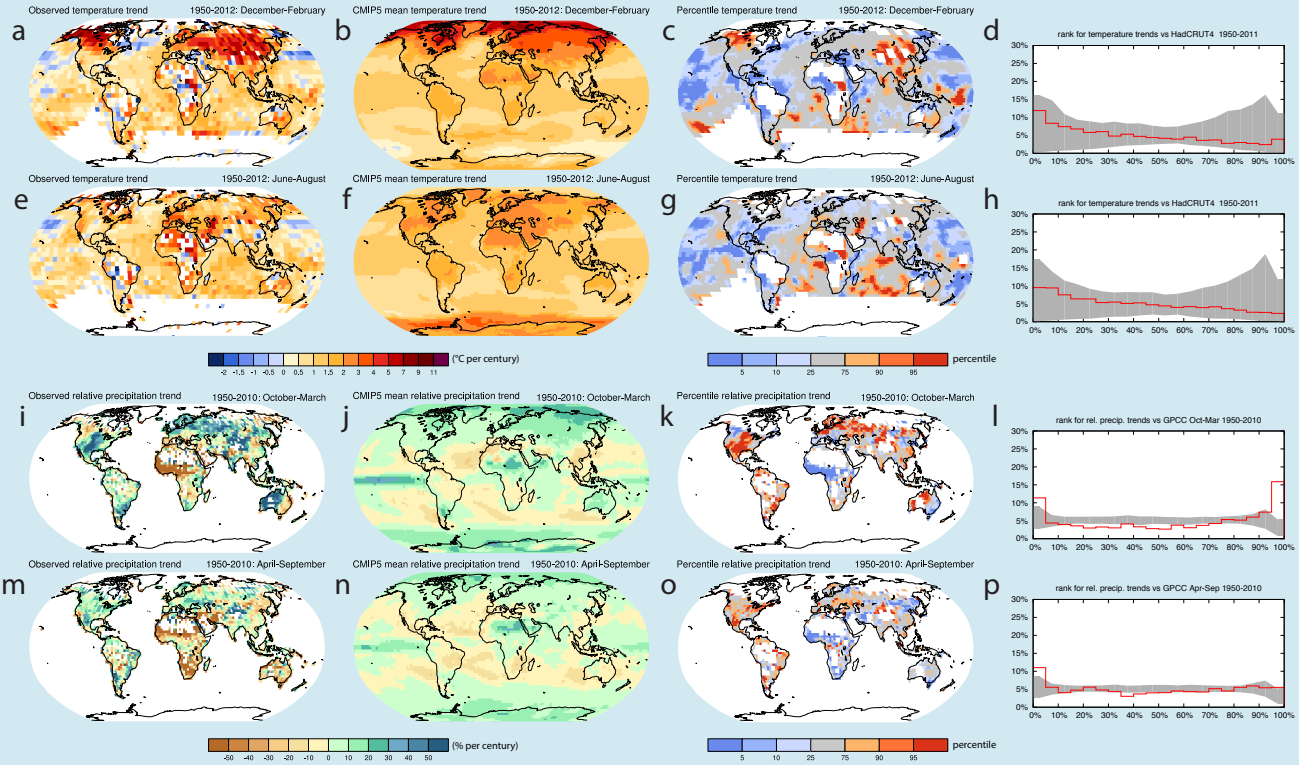
The assessed *likely* range for GMST in the period 2016–2035 may also be used to assess the likelihood that GMST will cross policy-relevant levels, relative to earlier time periods (Joshi et al., 2011). Using the 1850–1900 period, and the observed temperature rise between 1850–1900 and 1986–2005 of 0.61°C (estimated from the HadCRUT4 data set (Morice et al., 2012) gives a *likely* range for the GMST anomaly in 2016–2035 of 0.91°C–1.31°C, and supports the following conclusions: it is *more likely than not* that the mean GMST for the period 2016–2035 will be more than 1°C above the mean for 1850–1900, and *very unlikely* that it will be more than 1.5°C above the 1850–1900 mean (expert assessment, *medium confidence*). Additional information about the possibility of GMST crossing specific temperature levels is provided in Table 11.3, which shows the percentage of CMIP5 models for which the projected change in GMST exceeds specific temperature levels, under each RCP scenario, in two time periods (early century: 2016–2035 and mid-century: 2046–2065), and also using the two different reference periods discussed under point 6 and illustrated in Figure 11.25. However, these percentages should *not* be interpreted as likelihoods because—as discussed in this section—there are sources of uncertainty not captured by the CMIP5 ensemble. Note finally that it is *very likely* that specific temperature levels will be crossed temporarily in individual years before a permanent crossing is established (Joshi et al., 2011), but Table 11.3 is based on 20-year mean values.

Box 11.2 | Ability of Climate Models to Simulate Observed Regional Trends

The ability of models to simulate past climate change on regional scales can be used to investigate whether the multi-model ensemble spread covers the forcing and model uncertainties. Agreement between observed and simulated regional trends, taking natural variability and model spread into account, would build confidence in near-term projections. Although large-scale features are simulated well (see Chapter 10), on sub-continental and smaller scales the observed trends are, in general, more often in the tails of the distribution of modelled trends than would be expected by chance fluctuations (Bhend and Whetton, 2012; Knutson et al., 2013b; van Oldenborgh et al., 2013). Natural variability and model spread are larger at smaller scales (Stott et al., 2010), but this is not enough to bridge the gap between models and observations. Downscaling with Regional Climate Models (RCMs) does not affect seasonal mean trends except near mountains or coastlines in Europe (van Oldenborgh et al., 2009; van Haren et al., 2012). These results hold for both observed and modelled estimates of natural variability and for various analyses of the observations. Given the statistical nature of the comparisons, it is currently not possible to say in which regions observed discrepancies are due to coincidental natural variability and in which regions they are due to forcing or model deficiencies. These results show that in general the Coupled Model Intercomparison Project Phase 5 (CMIP5) ensemble cannot be taken as a reliable regional probability forecast, but that the true uncertainty can be larger than the model spread indicated in the maps in this chapter and Annex I.

Temperature

Räisänen (2007) and Yokohata et al. (2012) compared regional linear temperature trends during 1955–2005 (1961–2000) with corresponding trends in the CMIP3 ensemble. They found that the range of simulated trends captured the observed trend in nearly all locations. Using another metric, Knutson et al., (2013b) found that CMIP5 models did slightly better than CMIP3 in reproducing linear trends (see also Figure 10.2, Section 10.3.1.1.2). The linear CMIP5 temperature trends are compared with the observed trends in Box 11.2, Figure 1a–h. The rank histograms show the warm bias in global mean temperature (see Chapter 10) and some overconfidence, but within the inter-model spread. However, the apparent agreement appears to be for the wrong reason. Many of the models that appear to correctly simulate observed high regional trends do so because they have a high climate response (i.e., the global temperature rises quickly) and do not simulate the observed spatial pattern of trends (Kumar et al., 2013). To address this, Bhend and Whetton (2012) and van Oldenborgh et al. (2013) use another definition of the local trend: the regression of the local temperature on the (low-pass filtered) global mean temperature. This definition separates the local temperature response pattern from the global mean climate response. They find highly significant discrepancies between the CMIP3 and CMIP5 trend patterns and a variety of estimates of observed trend estimates. These discrepancies are defined relative to an error model that includes the (modelled or observed) natural variability, model spread and spatial autocorrelations. In the following, areas where the observed and modelled trends show marked differences are noted. Areas of agreement are covered in Section 10.3.1.1.4.



In December to February the observed Arctic amplification extends further south than modelled in Central Asia and northwestern North America. In June to August southern Europe and North Africa have warmed significantly faster than both CMIP3 and CMIP5 models simulated (van Oldenborgh et al., 2009); this also holds for the Middle East. The observed Indo-Pacific warm pool trend is significantly higher than the modelled trend year-round (Shin and Sardeshmukh, 2011; Williams and Funk, 2011), and the North Pacific and the southeastern USA and adjoining ocean trends were lower. Direct causes for many of these discrepancies are known (e.g., December to February circulation trends that differ between the observation and the models (Gillett et al., 2005; Gillett and Stott, 2009; van Oldenborgh et al., 2009; Bhend and Whetton, 2012) or teleconnections from other areas with trend biases (Deser and Phillips, 2009; Meehl et al., 2012a), but the causes of the underlying discrepancies are often unknown. Possibilities include observational uncertainties (note, however, that the areas where the observations warm more than the models do not correspond to areas of increased urbanization or irrigation; cf. Section 2.4.1.3), an underestimation of the low-frequency variability (Knutson et al. (2013b) show evidence that this is probably not the case for temperature outside the tropics), unrealistic local forcing (e.g., aerosols (Ruckstuhl and Norris, 2009)), or missing or misrepresented processes in models (e.g., fog (Vautard et al., 2009; Ceppi et al., 2012)).

Precipitation

In spite of the larger variability relative to the trends and observational uncertainties (cf. Section 2.5.1.2), annual mean regional linear precipitation trends have been found to differ significantly between observations and CMIP3 models, both in the zonal mean (Allan and Soden, 2007; Zhang et al., 2007b) and regionally (Räisänen, 2007). The comparison is shown in Box 11.2, Figure 1i–p for the CMIP5 half-year seasons used in Annex I, following van Oldenborgh et al. (2013). In both half years the observations fall more often in the highest and lowest 5% than expected by chance fluctuations within the ensemble (grey area). The differences larger than the difference between the CRU and GPCC analyses (cf. Figure 2.29) are noted below. *(continued on next page)*

Box 11.2 (continued)

In Europe there are large-scale differences between observed trends and trends, both in General Circulation Models (GCMs) and RCMs (Bhend and von Storch, 2008), which are ascribed to circulation change discrepancies in winter and in summer sea surface temperature (SST) trend biases (Lenderink et al., 2009; van Haren et al., 2012) and the misrepresentation of Summer North Atlantic Oscillation (NAO) teleconnections (Bladé et al., 2012). Central North America has become much wetter over 1950–2012, especially in winter, which is not simulated by the CMIP5 models. Larger observed northwest Australian rainfall increases than in CMIP3 in summer are driven by ozone forcings in two climate models (Kang et al., 2011) and aerosols in another (Rotstayn et al., 2012). The Guinea Coast has become drier in the observations than in the models. The CMIP5 patterns seem to reproduce the observed patterns somewhat better than the CMIP3 patterns (Bhend and Whetton, 2012), but the remaining discrepancies imply that CMIP5 projections cannot be used as reliable precipitation forecasts.

Box 11.2, Figure 1 | (a) Observed linear December to February temperature trend 1950–2012 (Hadley Centre/Climate Research Unit gridded surface temperature data set 4.1.1.0 (HadCRUT4.1.1.0, °C per century). (b) The equivalent CMIP5 ensemble mean trend. (c) Quantile of the observed trend in the ensemble, and (d) the corresponding rank histogram, the grey band denotes the 90% band of intermodel fluctuations (following Annan and Hargreaves, 2010). (e–h) Same for June to August. (i–l) Same for October to March precipitation (Global Precipitation Climatology Centre (GPCC) v7) 1950–2010, % per century). (m–p) Precipitation in April to September. Grid boxes where less than 50% of the years have observations are left white. (Based on Räisänen (2007) and van Oldenborgh et al. (2013).)

Acknowledgements

The authors thank Ed Hawkins (U. Reading, UK) for extensive input to discussions on the assessment of near-term global temperature and his work on key synthesis figures, and Jan Sedlacek (ETH, Switzerland) for his outstanding work on the production of numerous figures in this chapter.

Executive Summary

This chapter assesses long-term projections of climate change for the end of the 21st century and beyond, where the forced signal depends on the scenario and is typically larger than the internal variability of the climate system. Changes are expressed with respect to a baseline period of 1986–2005, unless otherwise stated.

Scenarios, Ensembles and Uncertainties

The Coupled Model Intercomparison Project Phase 5 (CMIP5) presents an unprecedented level of information on which to base projections including new Earth System Models with a more complete representation of forcings, new Representative Concentration Pathways (RCP) scenarios and more output available for analysis. The four RCP scenarios used in CMIP5 lead to a total radiative forcing (RF) at 2100 that spans a wider range than that estimated for the three Special Report on Emission Scenarios (SRES) scenarios (B1, A1B, A2) used in the Fourth Assessment Report (AR4), RCP2.6 being almost 2 W m^{-2} lower than SRES B1 by 2100. The magnitude of future aerosol forcing decreases more rapidly in RCP scenarios, reaching lower values than in SRES scenarios through the 21st century. Carbon dioxide (CO_2) represents about 80 to 90% of the total anthropogenic forcing in all RCP scenarios through the 21st century. The ensemble mean total effective RFs at 2100 for CMIP5 concentration-driven projections are 2.2, 3.8, 4.8 and 7.6 W m^{-2} for RCP2.6, RCP4.5, RCP6.0 and RCP8.5 respectively, relative to about 1850, and are close to corresponding Integrated Assessment Model (IAM)-based estimates (2.4, 4.0, 5.2 and 8.0 W m^{-2}). {12.2.1, 12.3, Table 12.1, Figures 12.1, 12.2, 12.3, 12.4}

New experiments and studies have continued to work towards a more complete and rigorous characterization of the uncertainties in long-term projections, but the magnitude of the uncertainties has not changed significantly since AR4. There is overall consistency between the projections based on CMIP3 and CMIP5, for both large-scale patterns and magnitudes of change. Differences in global temperature projections are largely attributable to a change in scenarios. Model agreement and confidence in projections depend on the variable and spatial and temporal averaging. The well-established stability of large-scale geographical patterns of change during a transient experiment remains valid in the CMIP5 models, thus justifying pattern scaling to approximate changes across time and scenarios under such experiments. Limitations remain when pattern scaling is applied to strong mitigation scenarios, to scenarios where localized forcing (e.g., aerosols) are significant and vary in time and for variables other than average temperature and precipitation. {12.2.2, 12.2.3, 12.4.2, 12.4.9, Figures 12.10, 12.39, 12.40, 12.41}

Projections of Temperature Change

Global mean temperatures will continue to rise over the 21st century if greenhouse gas (GHG) emissions continue unabated. Under the assumptions of the concentration-driven RCPs, global mean surface temperatures for 2081–2100, relative to 1986–2005 will *likely*[1] be in the 5 to 95% range of the CMIP5 models; 0.3°C to 1.7°C (RCP2.6), 1.1°C to 2.6°C (RCP4.5), 1.4°C to 3.1°C (RCP6.0), 2.6°C to 4.8°C (RCP8.5). Global temperatures averaged over the period 2081–2100 are projected to *likely* exceed 1.5°C above 1850-1900 for RCP4.5, RCP6.0 and RCP8.5 (*high confidence*), are *likely* to exceed 2°C above 1850-1900 for RCP6.0 and RCP8.5 (*high confidence*) and are *more likely than not* to exceed 2°C for RCP4.5 (*medium confidence*). Temperature change above 2°C under RCP2.6 is *unlikely* (*medium confidence*). Warming above 4°C by 2081–2100 is *unlikely* in all RCPs (*high confidence*) except for RCP8.5, where it is *about as likely as not* (*medium confidence*). {12.4.1, Tables 12.2, 12.3, Figures 12.5, 12.8}

Temperature change will not be regionally uniform. There is *very high confidence*[2] that globally averaged changes over land will exceed changes over the ocean at the end of the 21st century by a factor that is *likely* in the range 1.4 to 1.7. In the absence of a strong reduction in the Atlantic Meridional Overturning, the Arctic region is projected to warm most (*very high confidence*). This polar amplification is not found in Antarctic regions due to deep ocean mixing, ocean heat uptake and the persistence of the Antarctic ice sheet. Projected regional surface air temperature increase has minima in the North Atlantic and Southern Oceans in all scenarios. One model exhibits marked cooling in 2081–2100 over large parts of the Northern Hemisphere (NH), and a few models indicate slight cooling locally in the North Atlantic. Atmospheric zonal mean temperatures show warming throughout the troposphere, especially in the upper troposphere and northern high latitudes, and cooling in the stratosphere. {12.4.2, 12.4.3, Table 12.2, Figures 12.9, 12.10, 12.11, 12.12}

It is *virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global mean temperatures increase. These changes are expected for events defined as extremes on both daily and seasonal time scales. Increases in the frequency, duration and magnitude of hot extremes along with heat stress are expected; however, occasional cold winter extremes will continue to occur. Twenty-year return values of low temperature events are projected to increase at a rate greater than winter mean temperatures in most regions, with the largest changes in the return values of low temperatures at high latitudes. Twenty-year return values for high temperature events are projected to increase at a rate similar to or greater than the rate of increase of summer mean temperatures in most regions. Under RCP8.5 it is *likely* that, in most land regions, a current 20-year high temperature event will occur more frequently by the end of the 21st

[1] In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

[2] In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

century (at least doubling its frequency, but in many regions becoming an annual or 2-year event) and a current 20-year low temperature event will become exceedingly rare. {12.4.3, Figures 12.13, 12.14}

Changes in Atmospheric Circulation

Mean sea level pressure is projected to decrease in high latitudes and increase in the mid-latitudes as global temperatures rise. In the tropics, the Hadley and Walker Circulations are *likely* to slow down. Poleward shifts in the mid-latitude jets of about 1 to 2 degrees latitude are *likely* at the end of the 21st century under RCP8.5 in both hemispheres (*medium confidence*), with weaker shifts in the NH. In austral summer, the additional influence of stratospheric ozone recovery in the Southern Hemisphere opposes changes due to GHGs there, though the net response varies strongly across models and scenarios. Substantial uncertainty and thus *low confidence* remains in projecting changes in NH storm tracks, especially for the North Atlantic basin. The Hadley Cell is *likely* to widen, which translates to broader tropical regions and a poleward encroachment of subtropical dry zones. In the stratosphere, the Brewer–Dobson circulation is *likely* to strengthen. {12.4.4, Figures 12.18, 12.19, 12.20}

Changes in the Water Cycle

It is *virtually certain* that, in the long term, global precipitation will increase with increased global mean surface temperature. Global mean precipitation will increase at a rate per degree Celsius smaller than that of atmospheric water vapour. It will *likely* increase by 1 to 3% $°C^{-1}$ for scenarios other than RCP2.6. For RCP2.6 the range of sensitivities in the CMIP5 models is 0.5 to 4% $°C^{-1}$ at the end of the 21st century. {12.4.1, Figures 12.6, 12.7}

Changes in average precipitation in a warmer world will exhibit substantial spatial variation. Some regions will experience increases, other regions will experience decreases and yet others will not experience significant changes at all. There is *high confidence* that the contrast of annual mean precipitation between dry and wet regions and that the contrast between wet and dry seasons will increase over most of the globe as temperatures increase. The general pattern of change indicates that high latitude land masses are *likely* to experience greater amounts of precipitation due to the increased specific humidity of the warmer troposphere as well as increased transport of water vapour from the tropics by the end of this century under the RCP8.5 scenario. Many mid-latitude and subtropical arid and semi-arid regions will *likely* experience less precipitation and many moist mid-latitude regions will *likely* experience more precipitation by the end of this century under the RCP8.5 scenario. Globally, for short-duration precipitation events, a shift to more intense individual storms and fewer weak storms is *likely* as temperatures increase. Over most of the mid-latitude land-masses and over wet tropical regions, extreme precipitation events will *very likely* be more intense and more frequent in a warmer world. The global average sensitivity of the 20-year return value of the annual maximum daily precipitation increases ranges from 4% $°C^{-1}$ of local temperature increase (average of CMIP3 models) to 5.3% $°C^{-1}$ of local temperature increase (average of CMIP5 models) but regionally there are wide variations. {12.4.5, Figures 12.10, 12.22, 12.26, 12.27}

Annual surface evaporation is projected to increase as global temperatures rise over most of the ocean and is projected to change over land following a similar pattern as precipitation. Decreases in annual runoff are *likely* in parts of southern Europe, the Middle East, and southern Africa by the end of the 21st century under the RCP8.5 scenario. Increases in annual runoff are *likely* in the high northern latitudes corresponding to large increases in winter and spring precipitation by the end of the 21st century under the RCP8.5 scenario. Regional to global-scale projected decreases in soil moisture and increased risk of agricultural drought are *likely* in presently dry regions and are projected with *medium confidence* by the end of the 21st century under the RCP8.5 scenario. Prominent areas of projected decreases in evaporation include southern Africa and north western Africa along the Mediterranean. Soil moisture drying in the Mediterranean, southwest USA and southern African regions is consistent with projected changes in Hadley Circulation and increased surface temperatures, so surface drying in these regions as global temperatures increase is *likely* with *high confidence* by the end of this century under the RCP8.5 scenario. In regions where surface moistening is projected, changes are generally smaller than natural variability on the 20-year time scale. {12.4.5, Figures 12.23, 12.24, 12.25}

Changes in Cryosphere

It is *very likely* that the Arctic sea ice cover will continue shrinking and thinning year-round in the course of the 21st century as global mean surface temperature rises. At the same time, in the Antarctic, a decrease in sea ice extent and volume is expected, but with *low confidence*. Based on the CMIP5 multi-model ensemble, projections of average reductions in Arctic sea ice extent for 2081–2100 compared to 1986–2005 range from 8% for RCP2.6 to 34% for RCP8.5 in February and from 43% for RCP2.6 to 94% for RCP8.5 in September (*medium confidence*). A nearly ice-free Arctic Ocean (sea ice extent less than 1×10^6 km^2 for at least 5 consecutive years) in September before mid-century is *likely* under RCP8.5 (*medium confidence*), based on an assessment of a subset of models that most closely reproduce the climatological mean state and 1979–2012 trend of the Arctic sea ice cover. Some climate projections exhibit 5- to 10-year periods of sharp summer Arctic sea ice decline—even steeper than observed over the last decade—and it is *likely* that such instances of rapid ice loss will occur in the future. There is little evidence in global climate models of a tipping point (or critical threshold) in the transition from a perennially ice-covered to a seasonally ice-free Arctic Ocean beyond which further sea ice loss is unstoppable and irreversible. In the Antarctic, the CMIP5 multi-model mean projects a decrease in sea ice extent that ranges from 16% for RCP2.6 to 67% for RCP8.5 in February and from 8% for RCP2.6 to 30% for RCP8.5 in September for 2081–2100 compared to 1986–2005. There is, however, *low confidence* in those values as projections because of the wide inter-model spread and the inability of almost all of the available models to reproduce the mean annual cycle, interannual variability and overall increase of the Antarctic sea ice areal coverage observed during the satellite era. {12.4.6, 12.5.5, Figures 12.28, 12.29, 12.30, 12.31}

It is *very likely* that NH snow cover will reduce as global temperatures rise over the coming century. A retreat of permafrost extent with rising global temperatures is *virtually certain.* Snow

cover changes result from precipitation and ablation changes, which are sometimes opposite. Projections of the NH spring snow covered area by the end of the 21st century vary between a decrease of 7% (RCP2.6) and a decrease of 25% (RCP8.5), with a pattern that is fairly consistent between models. The projected changes in permafrost are a response not only to warming but also to changes in snow cover, which exerts a control on the underlying soil. By the end of the 21st century, diagnosed near-surface permafrost area is projected to decrease by between 37% (RCP2.6) and 81% (RCP8.5) (*medium confidence*). {12.4.6, Figures 12.32, 12.33}

Changes in the Ocean

The global ocean will warm in all RCP scenarios. The strongest ocean warming is projected for the surface in subtropical and tropical regions. At greater depth the warming is projected to be most pronounced in the Southern Ocean. Best estimates of ocean warming in the top one hundred meters are about 0.6°C (RCP2.6) to 2.0°C (RCP8.5), and about 0.3°C (RCP2.6) to 0.6°C (RCP8.5) at a depth of about 1 km by the end of the 21st century. For RCP4.5 by the end of the 21st century, half of the energy taken up by the ocean is in the uppermost 700 m and 85% is in the uppermost 2000 m. Due to the long time scales of this heat transfer from the surface to depth, ocean warming will continue for centuries, even if GHG emissions are decreased or concentrations kept constant. {12.4.7, 12.5.2–12.5.4, Figure 12.12}

It is *very likely* that the Atlantic Meridional Overturning Circulation (AMOC) will weaken over the 21st century but it is *very unlikely* that the AMOC will undergo an abrupt transition or collapse in the 21st century. Best estimates and ranges for the reduction from CMIP5 are 11% (1 to 24%) in RCP2.6 and 34% (12 to 54%) in RCP8.5. There is *low confidence* in assessing the evolution of the AMOC beyond the 21st century. {12.4.7, Figure 12.35}

Carbon Cycle

When forced with RCP8.5 CO_2 emissions, as opposed to the RCP8.5 CO_2 concentrations, 11 CMIP5 Earth System Models with interactive carbon cycle simulate, on average, a 50 ppm (min to max range –140 to +210 ppm) larger atmospheric CO_2 concentration and 0.2°C (min to max range –0.4 to +0.9°C) larger global surface temperature increase by 2100. {12.4.8, Figures 12.36, 12.37}

Long-term Climate Change, Commitment and Irreversibility

Global temperature equilibrium would be reached only after centuries to millennia if RF were stabilized. Continuing GHG emissions beyond 2100, as in the RCP8.5 extension, induces a total RF above 12 W m^{-2} by 2300. Sustained negative emissions beyond 2100, as in RCP2.6, induce a total RF below 2 W m^{-2} by 2300. The projected warming for 2281–2300, relative to 1986–2005, is 0.0°C to 1.2°C for RCP2.6 and 3.0°C to 12.6°C for RCP8.5 (*medium confidence*). In much the same way as the warming to a rapid increase of forcing is delayed, the cooling after a decrease of RF is also delayed. {12.5.1, Figures 12.43, 12.44}

A large fraction of climate change is largely irreversible on human time scales, unless net anthropogenic CO_2 emissions were strongly negative over a sustained period. For scenarios driven by CO_2 alone, global average temperature is projected to remain approximately constant for many centuries following a complete cessation of emissions. The positive commitment from CO_2 may be enhanced by the effect of an abrupt cessation of aerosol emissions, which will cause warming. By contrast, cessation of emission of short-lived GHGs will contribute a cooling. {12.5.3, 12.5.4, Figures 12.44, 12.45, 12.46, FAQ 12.3}

Equilibrium Climate Sensitivity and Transient Climate Response

Estimates of the equilibrium climate sensitivity (ECS) based on observed climate change, climate models and feedback analysis, as well as paleoclimate evidence indicate that ECS is *likely* in the range 1.5°C to 4.5°C with *high confidence*, *extremely unlikely* less than 1°C (*high confidence*) and *very unlikely* greater than 6°C (*medium confidence*). The transient climate response (TCR) is *likely* in the range 1°C to 2.5°C and *extremely unlikely* greater than 3°C, based on observed climate change and climate models. {Box 12.2, Figures 1, 2}

Climate Stabilization

The principal driver of long-term warming is total emissions of CO_2 and the two quantities are approximately linearly related. The global mean warming per 1000 PgC (transient climate response to cumulative carbon emissions (TCRE)) is *likely* between 0.8°C to 2.5°C per 1000 PgC, for cumulative emissions less than about 2000 PgC until the time at which temperatures peak. To limit the warming caused by anthropogenic CO_2 emissions alone to be *likely* less than 2°C relative to the period 1861-1880, total CO_2 emissions from all anthropogenic sources would need to be limited to a cumulative budget of about 1000 PgC since that period. About half [445 to 585 PgC] of this budget was already emitted by 2011. Accounting for projected warming effect of non-CO_2 forcing, a possible release of GHGs from permafrost or methane hydrates, or requiring a higher likelihood of temperatures remaining below 2°C, all imply a lower budget. {12.5.4, Figures 12.45, 12.46, Box 12.2}

Some aspects of climate will continue to change even if temperatures are stabilized. Processes related to vegetation change, changes in the ice sheets, deep ocean warming and associated sea level rise and potential feedbacks linking for example ocean and the ice sheets have their own intrinsic long time scales and may result in significant changes hundreds to thousands of years after global temperature is stabilized. {12.5.2 to 12.5.4}

Abrupt Change

Several components or phenomena in the climate system could potentially exhibit abrupt or nonlinear changes, and some are known to have done so in the past. Examples include the AMOC, Arctic sea ice, the Greenland ice sheet, the Amazon forest and monsoonal circulations. For some events, there is information on potential consequences, but in general there is *low confidence* and little consensus on the likelihood of such events over the 21st century. {12.5.5, Table 12.4}

12.1 Introduction

Projections of future climate change are not like weather forecasts. It is not possible to make deterministic, definitive predictions of how climate will evolve over the next century and beyond as it is with short-term weather forecasts. It is not even possible to make projections of the frequency of occurrence of all possible outcomes in the way that it might be possible with a calibrated probabilistic medium-range weather forecast. Projections of climate change are uncertain, first because they are dependent primarily on scenarios of future anthropogenic and natural forcings that are uncertain, second because of incomplete understanding and imprecise models of the climate system and finally because of the existence of internal climate variability. The term climate projection tacitly implies these uncertainties and dependencies. Nevertheless, as greenhouse gas (GHG) concentrations continue to rise, we expect to see future changes to the climate system that are greater than those already observed and attributed to human activities. It is possible to understand future climate change using models and to use models to characterize outcomes and uncertainties under specific assumptions about future forcing scenarios.

This chapter assesses climate projections on time scales beyond those covered in Chapter 11, that is, beyond the mid-21st century. Information from a range of different modelling tools is used here; from simple energy balance models, through Earth System Models of Intermediate Complexity (EMICs) to complex dynamical climate and Earth System Models (ESMs). These tools are evaluated in Chapter 9 and, where possible, the evaluation is used in assessing the validity of the projections. This chapter also summarizes some of the information on leading-order measures of the sensitivity of the climate system from other chapters and discusses the relevance of these measures for climate projections, commitments and irreversibility.

Since the AR4 (Meehl et al., 2007b) there have been a number of advances:

- New scenarios of future forcings have been developed to replace the Special Report on Emissions Scenarios (SRES). The Representative Concentration Pathways (RCPs, see Section 12.3) (Moss et al., 2010), have been designed to cover a wide range of possible magnitudes of climate change in models rather than being derived sequentially from storylines of socioeconomic futures. The aim is to provide a range of climate responses while individual socioeconomic scenarios may be derived, scaled and interpolated (some including explicit climate policy). Nevertheless, many studies that have been performed since AR4 have used SRES and, where appropriate, these are assessed. Simplified scenarios of future change, developed strictly for understanding the response of the climate system rather than to represent realistic future outcomes, are also synthesized and the understanding of leading-order measures of climate response such as the equilibrium climate sensitivity (ECS) and the transient climate response (TCR) are assessed.

- New models have been developed with higher spatial resolution, with better representation of processes and with the inclusion of more processes, in particular processes that are important in simulating the carbon cycle of the Earth. In these models, emissions of GHGs may be specified and these gases may be chemically active in the atmosphere or be exchanged with pools in terrestrial and oceanic systems before ending up as an airborne concentration (see Figure 10.1 of AR4).

- New types of model experiments have been performed, many coordinated by the Coupled Model Intercomparison Project Phase 5 (CMIP5) (Taylor et al., 2012), which exploit the addition of these new processes. Models may be driven by emissions of GHGs, or by their concentrations with different Earth System feedback loops cut. This allows the separate assessment of different feedbacks in the system and of projections of physical climate variables and future emissions.

- Techniques to assess and quantify uncertainties in projections have been further developed but a full probabilistic quantification remains difficult to propose for most quantities, the exception being global, temperature-related measures of the system sensitivity to forcings, such as ECS and TCR. In those few cases, projections are presented in the form of probability density functions (PDFs). We make the distinction between the spread of a multi-model ensemble, an *ad hoc* measure of the possible range of projections and the quantification of uncertainty that combines information from models and observations using statistical algorithms. Just like climate models, different techniques for quantifying uncertainty exist and produce different outcomes. Where possible, different estimates of uncertainty are compared.

Although not an advance, as time has moved on, the baseline period from which climate change is expressed has also moved on (a common baseline period of 1986–2005 is used throughout, consistent with the 2006 start-point for the RCP scenarios). Hence climate change is expressed as a change with respect to a recent period of history, rather than a time before significant anthropogenic influence. It should be borne in mind that some anthropogenically forced climate change had already occurred by the 1986–2005 period (see Chapter 10).

The focus of this chapter is on global and continental/ocean basin-scale features of climate. For many aspects of future climate change, it is possible to discuss generic features of projections and the processes that underpin them for such large scales. Where interesting or unique changes have been investigated at smaller scales, and there is a level of agreement between different studies of those smaller-scale changes, these may also be assessed in this chapter, although where changes are linked to climate phenomena such as El Niño, readers are referred to Chapter 14. Projections of atmospheric composition, chemistry and air quality for the 21st century are assessed in Chapter 11, except for CO_2 which is assessed in this chapter. An innovation for AR5 is Annex I: Atlas of Global and Regional Climate Projections, a collection of global and regional maps of projected climate changes derived from model output. A detailed commentary on each of the maps presented in Annex I is not provided here, but some discussion of generic features is provided.

Projections from regional models driven by boundary conditions from global models are not extensively assessed but may be mentioned in this chapter. More detailed regional information may be found in Chapter 14 and is also now assessed in the Working Group II report, where it can more easily be linked to impacts.

12.2 Climate Model Ensembles and Sources of Uncertainty from Emissions to Projections

12.2.1 The Coupled Model Intercomparison Project Phase 5 and Other Tools

Many of the figures presented in this chapter and in others draw on data collected as part of CMIP5 (Taylor et al., 2012). The project involves the worldwide coordination of ESM experiments including the coordination of input forcing fields, diagnostic output and the hosting of data in a distributed archive. CMIP5 has been unprecedented in terms of the number of modelling groups and models participating, the number of experiments performed and the number of diagnostics collected. The archive of model simulations began being populated by mid-2011 and continued to grow during the writing of AR5. The production of figures for this chapter draws on a fixed database of simulations and variables that was available on 15 March 2013 (the same as the cut-off date for the acceptance of the publication of papers). Different figures may use different subsets of models and there are unequal numbers of models that have produced output for the different RCP scenarios. Figure 12.1 gives a summary of which output was available from which model for which scenario. Where multiple runs are performed with exactly the same model but with different initial conditions, we choose only one ensemble member (usually the first but in cases where that was not available, the first available member is chosen) in order not to weight models with more ensemble members than others unduly in the multi-model synthesis. Rather than give an exhaustive account of which models were used to make which figures, this summary information is presented as a guide to readers.

In addition to output from CMIP5, information from a coordinated set of simulations with EMICs is also used (Zickfeld et al., 2013) to investigate long-term climate change beyond 2100. Even more simplified energy balance models or emulation techniques are also used, mostly to estimate responses where ESM experiments are not available (Meinshausen et al., 2011a; Good et al., 2013). An evaluation of the models used for projections is provided in Chapter 9 of this Report.

12.2.2 General Concepts: Sources of Uncertainties

The understanding of the sources of uncertainty affecting future climate change projections has not substantially changed since AR4, but many experiments and studies since then have proceeded to explore and characterize those uncertainties further. A full characterization,

Figure 12.1 | A summary of the output used to make the CMIP5 figures in this chapter (and some figures in Chapter 11). The climate variable names run along the horizontal axis and use the standard abbreviations in the CMIP5 protocol (Taylor et al., 2012, and online references therein). The climate model names run along the vertical axis. In each box the shading indicates the number of ensemble members available for historical, RCP2.6, RCP4.5, RCP6.0, RCP8.5 and pre-industrial control experiments, although only one ensemble member per model is used in the relevant figures.

Frequently Asked Questions

FAQ 12.1 | Why Are So Many Models and Scenarios Used to Project Climate Change?

Future climate is partly determined by the magnitude of future emissions of greenhouse gases, aerosols and other natural and man-made forcings. These forcings are external to the climate system, but modify how it behaves. Future climate is shaped by the Earth's response to those forcings, along with internal variability inherent in the climate system. A range of assumptions about the magnitude and pace of future emissions helps scientists develop different emission scenarios, upon which climate model projections are based. Different climate models, meanwhile, provide alternative representations of the Earth's response to those forcings, and of natural climate variability. Together, ensembles of models, simulating the response to a range of different scenarios, map out a range of possible futures, and help us understand their uncertainties.

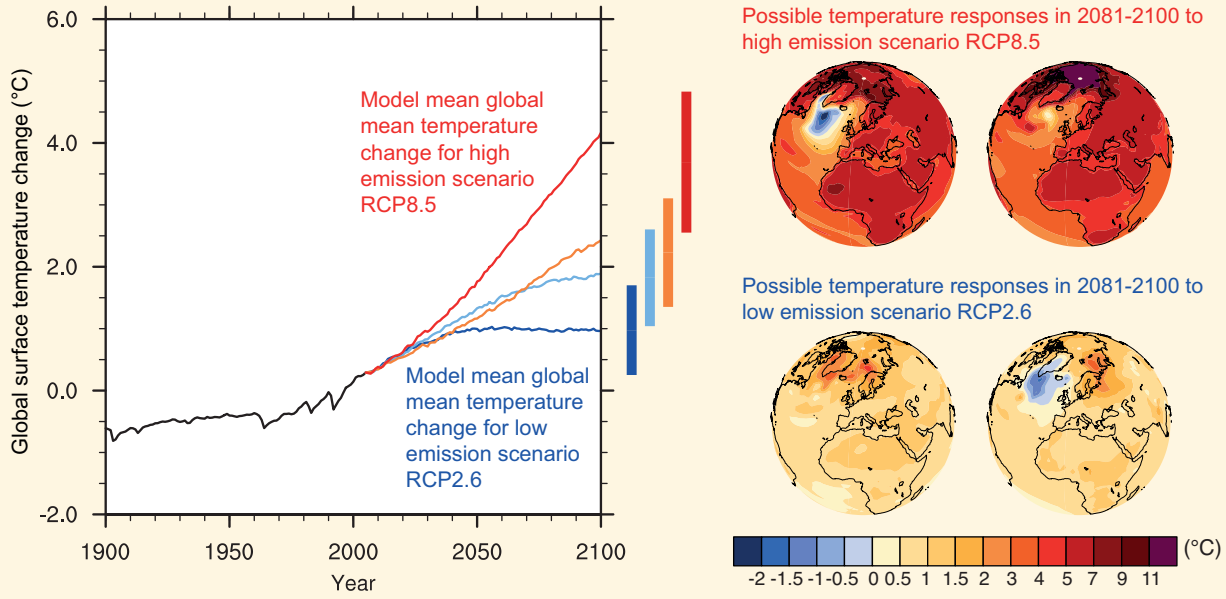
Predicting socioeconomic development is arguably even more difficult than predicting the evolution of a physical system. It entails predicting human behaviour, policy choices, technological advances, international competition and cooperation. The common approach is to use scenarios of plausible future socioeconomic development, from which future emissions of greenhouse gases and other forcing agents are derived. It has not, in general, been possible to assign likelihoods to individual forcing scenarios. Rather, a set of alternatives is used to span a range of possibilities. The outcomes from different forcing scenarios provide policymakers with alternatives and a range of possible futures to consider.

Internal fluctuations in climate are spontaneously generated by interactions between components such as the atmosphere and the ocean. In the case of near-term climate change, they may eclipse the effect of external perturbations, like greenhouse gas increases (see Chapter 11). Over the longer term, however, the effect of external forcings is expected to dominate instead. Climate model simulations project that, after a few decades, different scenarios of future anthropogenic greenhouse gases and other forcing agents—and the climate system's response to them—will differently affect the change in mean global temperature (FAQ 12.1, Figure 1, left panel). Therefore, evaluating the consequences of those various scenarios and responses is of paramount importance, especially when policy decisions are considered.

Climate models are built on the basis of the physical principles governing our climate system, and empirical understanding, and represent the complex, interacting processes needed to simulate climate and climate change, both past and future. Analogues from past observations, or extrapolations from recent trends, are inadequate strategies for producing projections, because the future will not necessarily be a simple continuation of what we have seen thus far.

Although it is possible to write down the equations of fluid motion that determine the behaviour of the atmosphere and ocean, it is impossible to solve them without using numerical algorithms through computer model simulation, similarly to how aircraft engineering relies on numerical simulations of similar types of equations. Also, many small-scale physical, biological and chemical processes, such as cloud processes, cannot be described by those equations, either because we lack the computational ability to describe the system at a fine enough resolution to directly simulate these processes or because we still have a partial scientific understanding of the mechanisms driving these processes. Those need instead to be approximated by so-called parameterizations within the climate models, through which a mathematical relation between directly simulated and approximated quantities is established, often on the basis of observed behaviour.

There are various alternative and equally plausible numerical representations, solutions and approximations for modelling the climate system, given the limitations in computing and observations. This diversity is considered a healthy aspect of the climate modelling community, and results in a range of plausible climate change projections at global and regional scales. This range provides a basis for quantifying uncertainty in the projections, but because the number of models is relatively small, and the contribution of model output to public archives is voluntary, the sampling of possible futures is neither systematic nor comprehensive. Also, some inadequacies persist that are common to all models; different models have different strength and weaknesses; it is not yet clear which aspects of the quality of the simulations that can be evaluated through observations should guide our evaluation of future model simulations. *(continued on next page)*



FAQ 12.1 (continued)

Models of varying complexity are commonly used for different projection problems. A faster model with lower resolution, or a simplified description of some climate processes, may be used in cases where long multi-century simulations are required, or where multiple realizations are needed. Simplified models can adequately represent large-scale average quantities, like global average temperature, but finer details, like regional precipitation, can be simulated only by complex models.

The coordination of model experiments and output by groups such as the Coupled Model Intercomparison Project (CMIP), the World Climate Research Program and its Working Group on Climate Models has seen the science community step up efforts to evaluate the ability of models to simulate past and current climate and to compare future climate change projections. The 'multi-model' approach is now a standard technique used by the climate science community to assess projections of a specific climate variable.

FAQ 12.1, Figure 1, right panels, shows the temperature response by the end of the 21st century for two illustrative models and the highest and lowest RCP scenarios. Models agree on large-scale patterns of warming at the surface, for example, that the land is going to warm faster than ocean, and the Arctic will warm faster than the tropics. But they differ both in the magnitude of their global response for the same scenario, and in small scale, regional aspects of their response. The magnitude of Arctic amplification, for instance, varies among different models, and a subset of models show a weaker warming or slight cooling in the North Atlantic as a result of the reduction in deepwater formation and shifts in ocean currents.

There are inevitable uncertainties in future external forcings, and the climate system's response to them, which are further complicated by internally generated variability. The use of multiple scenarios and models have become a standard choice in order to assess and characterize them, thus allowing us to describe a wide range of possible future evolutions of the Earth's climate.

FAQ 12.1, Figure 1 | Global mean temperature change averaged across all Coupled Model Intercomparison Project Phase 5 (CMIP5) models (relative to 1986–2005) for the four Representative Concentration Pathway (RCP) scenarios: RCP2.6 (dark blue), RCP4.5 (light blue), RCP6.0 (orange) and RCP8.5 (red); 32, 42, 25 and 39 models were used respectively for these 4 scenarios. *Likely* ranges for global temperature change by the end of the 21st century are indicated by vertical bars. Note that these ranges apply to the difference between two 20-year means, 2081–2100 relative to 1986–2005, which accounts for the bars being centred at a smaller value than the end point of the annual trajectories. For the highest (RCP8.5) and lowest (RCP2.6) scenario, illustrative maps of surface temperature change at the end of the 21st century (2081–2100 relative to 1986–2005) are shown for two CMIP5 models. These models are chosen to show a rather broad range of response, but this particular set is not representative of any measure of model response uncertainty.

qualitative and even more so quantitative, involves much more than a measure of the range of model outcomes, because additional sources of information (e.g., observational constraints, model evaluation, expert judgement) lead us to expect that the uncertainty around the future climate state does not coincide straightforwardly with those ranges. In fact, in this chapter we highlight wherever relevant the distinction between model uncertainty evaluation, which encompasses the understanding that models have intrinsic shortcoming in fully and accurately representing the real system, and cannot all be considered independent of one another (Knutti et al., 2013), and a simpler descriptive quantification, based on the range of outcomes from the ensemble of models.

Uncertainty affecting mid- to long-term projections of climatic changes stems from distinct but possibly interacting sources. Figure 12.2 shows a schematic of the chain from scenarios, through ESMs to projections. Uncertainties affecting near-term projections of which some aspect are also relevant for longer-term projections are discussed in Section 11.3.1.1 and shown in Figure 11.8.

Future anthropogenic emissions of GHGs, aerosol particles and other forcing agents such as land use change are dependent on socioeconomic factors including global geopolitical agreements to control those emissions. Systematic studies that attempt to quantify the likely ranges of anthropogenic emission have been undertaken (Sokolov et al., 2009) but it is more common to use a scenario approach of different but plausible—in the sense of technically feasible—pathways, leading to the concept of *scenario uncertainty*. AR4 made extensive use of the SRES scenarios (IPCC, 2000) developed using a sequential approach, that is, socioeconomic factors feed into emissions scenarios which are then used either to directly force the climate models or to determine concentrations of GHGs and other agents required to drive these models. This report also assesses outcomes of simulations that use the new RCP scenarios, developed using a parallel process (Moss et al., 2010) whereby different targets in terms of RF at 2100 were selected (2.6, 4.5, 6.0 and 8.5 W m^{-2}) and GHG and aerosol emissions consistent with those targets, and their corresponding socioeconomic drivers were developed simultaneously (see Section 12.3). Rather than being identified with one socioeconomic storyline, RCP scenarios are consistent with many possible economic futures (in fact, different combinations of GHG and aerosol emissions can lead to the same RCP). Their development was driven by the need to produce scenarios that could be input to climate model simulations more expediently while corresponding socioeconomic scenarios would be developed in parallel, and to produce a wide range of model responses that may be scaled and interpolated to estimate the response under other scenarios, involving different measures of adaptation and mitigation.

In terms of the uncertainties related to the RCP emissions scenarios, the following issues can be identified:

- No probabilities or likelihoods have been attached to the alternative RCP scenarios (as was the case for SRES scenarios). Each of them should be considered plausible, as no study has questioned their technical feasibility (see Chapter 1).

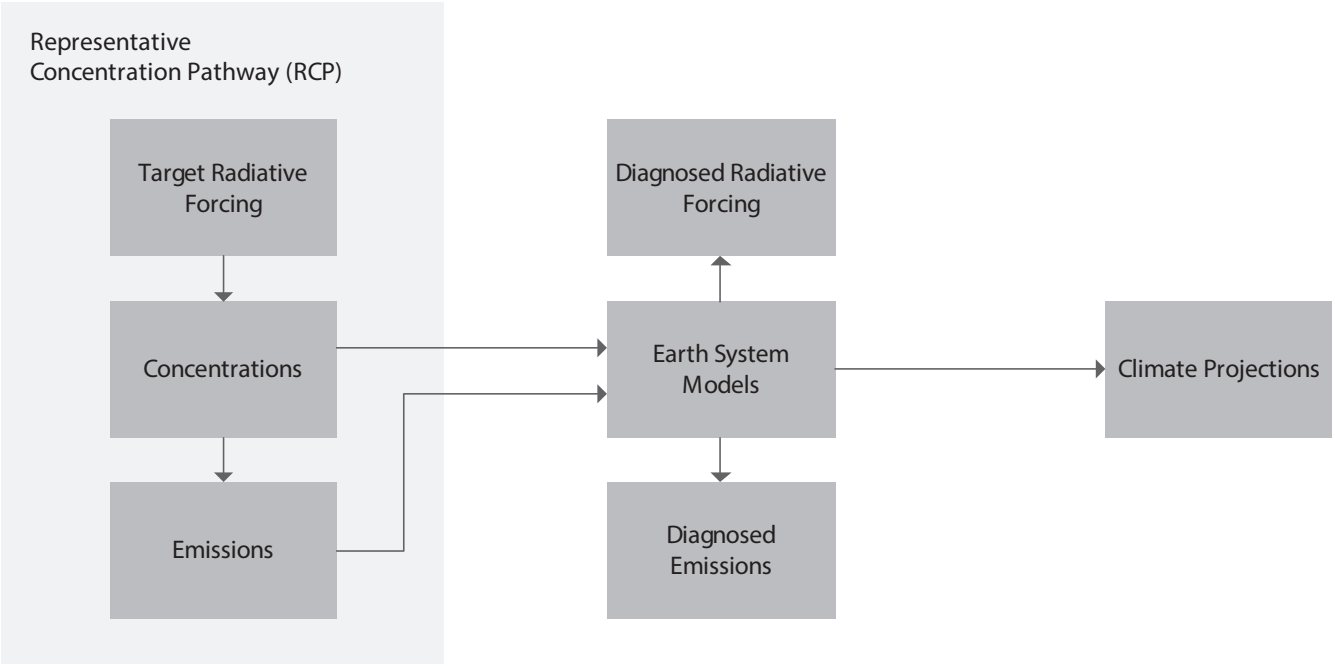


Figure 12.2 | Links in the chain from scenarios, through models to climate projections. The Representative Concentration Pathways (RCPs) are designed to sample a range of radiative forcing (RF) of the climate system at 2100. The RCPs are translated into both concentrations and emissions of greenhouse gases using Integrated Assessment Models (IAMs). These are then used as inputs to dynamical Earth System Models (ESMs) in simulations that are either concentration-driven (the majority of projection experiments) or emissions-driven (only for RCP8.5). Aerosols and other forcing factors are implemented in different ways in each ESM. The ESM projections each have a potentially different RF, which may be viewed as an output of the model and which may not correspond to precisely the level of RF indicated by the RCP nomenclature. Similarly, for concentration-driven experiments, the emissions consistent with those concentrations diagnosed from the ESM may be different from those specified in the RCP (diagnosed from the IAM). Different models produce different responses even under the same RF. Uncertainty propagates through the chain and results in a spread of ESM projections. This spread is only one way of assessing uncertainty in projections. Alternative methods, which combine information from simple and complex models and observations through statistical models or expert judgement, are also used to quantify that uncertainty.

- Despite the naming of the RCPs in terms of their target RF at 2100 or at stabilization (Box 1.1), climate models translate concentrations of forcing agents into RF in different ways due to their different structural modelling assumptions. Hence a model simulation of RCP6.0 may not attain exactly a RF of 6 W m^{-2}; more accurately, an RCP6.0 forced model experiment may not attain exactly the same RF as was intended by the specification of the RCP6.0 forcing inputs. Thus in addition to the scenario uncertainty there is RF uncertainty in the way the RCP scenarios are implemented in climate models.

- Some model simulations are concentration-driven (GHG concentrations are specified) whereas some models, which have Earth Systems components, convert emission scenarios into concentrations and are termed emissions-driven. Different ESMs driven by emissions may produce different concentrations of GHGs and aerosols because of differences in the representation and/or parameterization of the processes responsible for the conversion of emissions into concentrations. This aspect may be considered a facet of forcing uncertainty, or may be compounded in the category of model uncertainty, which we discuss below. Also, aerosol loading and land use changes are not dictated intrinsically by the RCP specification. Rather, they are a result of the Integrated Assessment Model that created the emission pathway for a given RCP.

SRES and RCPs account for future changes only in anthropogenic forcings. With regard to solar forcing, the 1985–2005 solar cycle is repeated. Neither projections of future deviations from this solar cycle, nor future volcanic RF and their uncertainties are considered.

Any climate projection is subject to sampling uncertainties that arise because of internal variability. In this chapter, the prediction of, for example, the amplitude or phase of some mode of variability that may be important on long time scales is not addressed (see Sections 11.2 and 11.3). Any climate variable projection derived from a single simulation of an individual climate model will be affected by internal variability (stemming from the chaotic nature of the system), whether it be a variable that involves a long time average (e.g., 20 years), a snapshot in time or some more complex diagnostic such as the variance computed from a time series over many years. No amount of time averaging can reduce internal variability to zero, although for some EMICs and simplified models, which may be used to reproduce the results of more complex model simulations, the representation of internal variability is excluded from the model specification by design. For different variables, and different spatial and time scale averages, the relative importance of internal variability in comparison with other sources of uncertainty will be different. In general, internal variability becomes more important on shorter time scales and for smaller scale variables (see Section 11.3 and Figure 11.2). The concept of signal-to-noise ratio may be used to quantify the relative magnitude of the forced response (signal) versus internal variability (noise). Internal variability may be sampled and estimated explicitly by running ensembles of simulations with slightly different initial conditions, designed explicitly to represent internal variability, or can be estimated on the basis of long control runs where external forcings are held constant. In the case of both multi-model and perturbed physics ensembles (see below), there is an implicit perturbation in the initial state of each run considered, which means that these ensembles sample both modelling uncertainty and internal variability jointly.

The ability of models to mimic nature is achieved by simplification choices that can vary from model to model in terms of the fundamental numeric and algorithmic structures, forms and values of parameterizations, and number and kinds of coupled processes included. Simplifications and the interactions between parameterized and resolved processes induce 'errors' in models, which can have a leading-order impact on projections. It is possible to characterize the choices made when building and running models into structural—indicating the numerical techniques used for solving the dynamical equations, the analytic form of parameterization schemes and the choices of inputs for fixed or varying boundary conditions—and parametric—indicating the choices made in setting the parameters that control the various components of the model. The community of climate modellers has regularly collaborated in producing coordinated experiments forming multi-model ensembles (MMEs), using both global and regional model families, for example, CMIP3/5 (Meehl et al., 2007a), ENSEMBLES (Johns et al., 2011) and Chemistry–Climate Model Validation 1 and 2 (CCM-Val-1 and 2; Eyring et al., 2005), through which structural uncertainty can be at least in part explored by comparing models, and perturbed physics ensembles (PPEs, with e.g., Hadley Centre Coupled Model version 3 (HadCM3; Murphy et al., 2004), Model for Interdiciplinary Research On Climate (MIROC; Yokohata et al., 2012), Community Climate System Model 3 (CCSM3; Jackson et al., 2008; Sanderson, 2011)), through which uncertainties in parameterization choices can be assessed in a given model. As noted below, neither MMEs nor PPEs represent an adequate sample of all the possible choices one could make in building a climate model. Also, current models may exclude some processes that could turn out to be important for projections (e.g., methane clathrate release) or produce a common error in the representation of a particular process. For this reason, it is of critical importance to distinguish two different senses in which the uncertainty terminology is used or misused in the literature (see also Sections 1.4.2, 9.2.2, 9.2.3, 11.2.1 and 11.2.2). A narrow interpretation of the concept of model uncertainty often identifies it with the range of responses of a model ensemble. In this chapter this type of characterization is referred as model range or model spread. A broader concept entails the recognition of a fundamental uncertainty in the representation of the real system that these models can achieve, given their necessary approximations and the limits in the scientific understanding of the real system that they encapsulate. When addressing this aspect and characterizing it, this chapter uses the term model uncertainty.

The relative role of the different sources of uncertainty—model, scenario and internal variability—as one moves from short- to mid- to long-term projections and considers different variables at different spatial scales has to be recognized (see Section 11.3). The three sources exchange relevance as the time horizon, the spatial scale and the variable change. In absolute terms, internal variability is generally estimated, and has been shown in some specific studies (Hu et al., 2012) to remain approximately constant across the forecast horizon, with model ranges and scenario/forcing variability increasing over time. For forecasts of global temperatures after mid-century, scenario and model ranges dominate the amount of variation due to internally generated variability, with scenarios accounting for the largest source

of uncertainty in projections by the end of the century. For global average precipitation projections, scenario uncertainty has a much smaller role even by the end of the 21st century and model range maintains the largest share across all projection horizons. For temperature and precipitation projections at smaller spatial scales, internal variability may remain a significant source of uncertainty up until middle of the 21st century in some regions (Hawkins and Sutton, 2009, 2011; Rowell, 2012; Knutti and Sedláček, 2013). Within single model experiments, the persistently significant role of internally generated variability for regional projections even beyond short- and mid-term horizons has been documented by analyzing relatively large ensembles sampling initial conditions (Deser et al., 2012a, 2012b).

12.2.3 From Ensembles to Uncertainty Quantification

Ensembles like CMIP5 do not represent a systematically sampled family of models but rely on self-selection by the modelling groups. This opportunistic nature of MMEs has been discussed, for example, in Tebaldi and Knutti (2007) and Knutti et al. (2010a). These ensembles are therefore not designed to explore uncertainty in a coordinated manner, and the range of their results cannot be straightforwardly interpreted as an exhaustive range of plausible outcomes, even if some studies have shown how they appear to behave as well calibrated probabilistic forecasts for some large-scale quantities (Annan and Hargreaves, 2010). Other studies have argued instead that the tail of distributions is by construction undersampled (Räisänen, 2007). In general, the difficulty in producing quantitative estimates of uncertainty based on multiple model output originates in their peculiarities as a statistical sample, neither random nor systematic, with possible dependencies among the members (Jun et al., 2008; Masson and Knutti, 2011; Pennell and Reichler, 2011; Knutti et al., 2013) and of spurious nature, that is, often counting among their members models with different degrees of complexities (different number of processes explicitly represented or parameterized) even within the category of general circulation models.

Agreement between multiple models can be a source of information in an uncertainty assessment or confidence statement. Various methods have been proposed to indicate regions where models agree on the projected changes, agree on no change or disagree. Several of those methods are compared in Box 12.1. Many figures use stippling or hatching to display such information, but it is important to note that confidence cannot be inferred from model agreement alone.

Perturbed physics experiments (PPEs) differ in their output interpretability for they can be, and have been, systematically constructed and as such lend themselves to a more straightforward treatment through statistical modelling (Rougier, 2007; Sanso and Forest, 2009). Uncertain parameters in a single model to whose values the output is known to be sensitive are targeted for perturbations. More often it is the parameters in the atmospheric component of the model that are varied (Collins et al., 2006a; Sanderson et al., 2008), and to date have in fact shown to be the source of the largest uncertainties in large-scale response, but lately, with much larger computing power expense, also parameters within the ocean component have been perturbed (Collins et al., 2007; Brierley et al., 2010). Parameters in the land surface schemes have also been subject to perturbation studies (Fischer et al., 2011; Booth et al., 2012; Lambert et al., 2012). Ranges of possible values are explored and often statistical models that fit the relationship between parameter values and model output, that is, emulators, are trained on the ensemble and used to predict the outcome for unsampled parameter value combinations, in order to explore the parameter space more thoroughly that would otherwise be computationally affordable (Rougier et al., 2009). The space of a single model simulations (even when filtered through observational constraints) can show a large range of outcomes for a given scenario (Jackson et al., 2008). However, multi-model ensembles and perturbed physics ensembles produce modes and distributions of climate responses that can be different from one another, suggesting that one type of ensemble cannot be used as an analogue for the other (Murphy et al., 2007; Sanderson et al., 2010; Yokohata et al., 2010; Collins et al., 2011).

Many studies have made use of results from these ensembles to characterize uncertainty in future projections, and these will be assessed and their results incorporated when describing specific aspects of future climate responses. PPEs have been uniformly treated across the different studies through the statistical framework of analysis of computer experiments (Sanso et al., 2008; Rougier et al., 2009; Harris et al., 2010) or, more plainly, as a thorough exploration of alternative responses reweighted by observational constraints (Murphy et al., 2004; Piani et al., 2005; Forest et al., 2008; Sexton et al., 2012). In all cases the construction of a probability distribution is facilitated by the systematic nature of the experiments. MMEs have generated a much more diversified treatment (1) according to the choice of applying weights to the different models on the basis of past performance or not (Weigel et al., 2010) and (2) according to the choice between treating the different models and the truth as indistinguishable or treating each model as a version of the truth to which an error has been added (Annan and Hargreaves, 2010; Sanderson and Knutti, 2012). Many studies can be classified according to these two criteria and their combination, but even within each of the four resulting categories different studies produce different estimates of uncertainty, owing to the preponderance of *a priori* assumptions, explicitly in those studies that approach the problem through a Bayesian perspective, or only implicit in the choice of likelihood models, or weighting. This makes the use of probabilistic and other results produced through statistical inference necessarily dependent on agreeing with a particular set of assumptions (Sansom et al., 2013), given the lack of a full exploration of the robustness of probabilistic estimates to varying these assumptions.

In summary, there does not exist at present a single agreed on and robust formal methodology to deliver uncertainty quantification estimates of future changes in all climate variables (see also Section 9.8.3 and Stephenson et al., 2012). As a consequence, in this chapter, statements using the calibrated uncertainty language are a result of the expert judgement of the authors, combining assessed literature results with an evaluation of models demonstrated ability (or lack thereof) in simulating the relevant processes (see Chapter 9) and model consensus (or lack thereof) over future projections. In some cases when a significant relation is detected between model performance and reliability of its future projections, some models (or a particular parametric configuration) may be excluded (e.g., Arctic sea ice; Section 12.4.6.1 and Joshi et al., 2010) but in general it remains an open research question to find significant connections of this kind that justify some form of weighting across the ensemble of models and produce aggregated

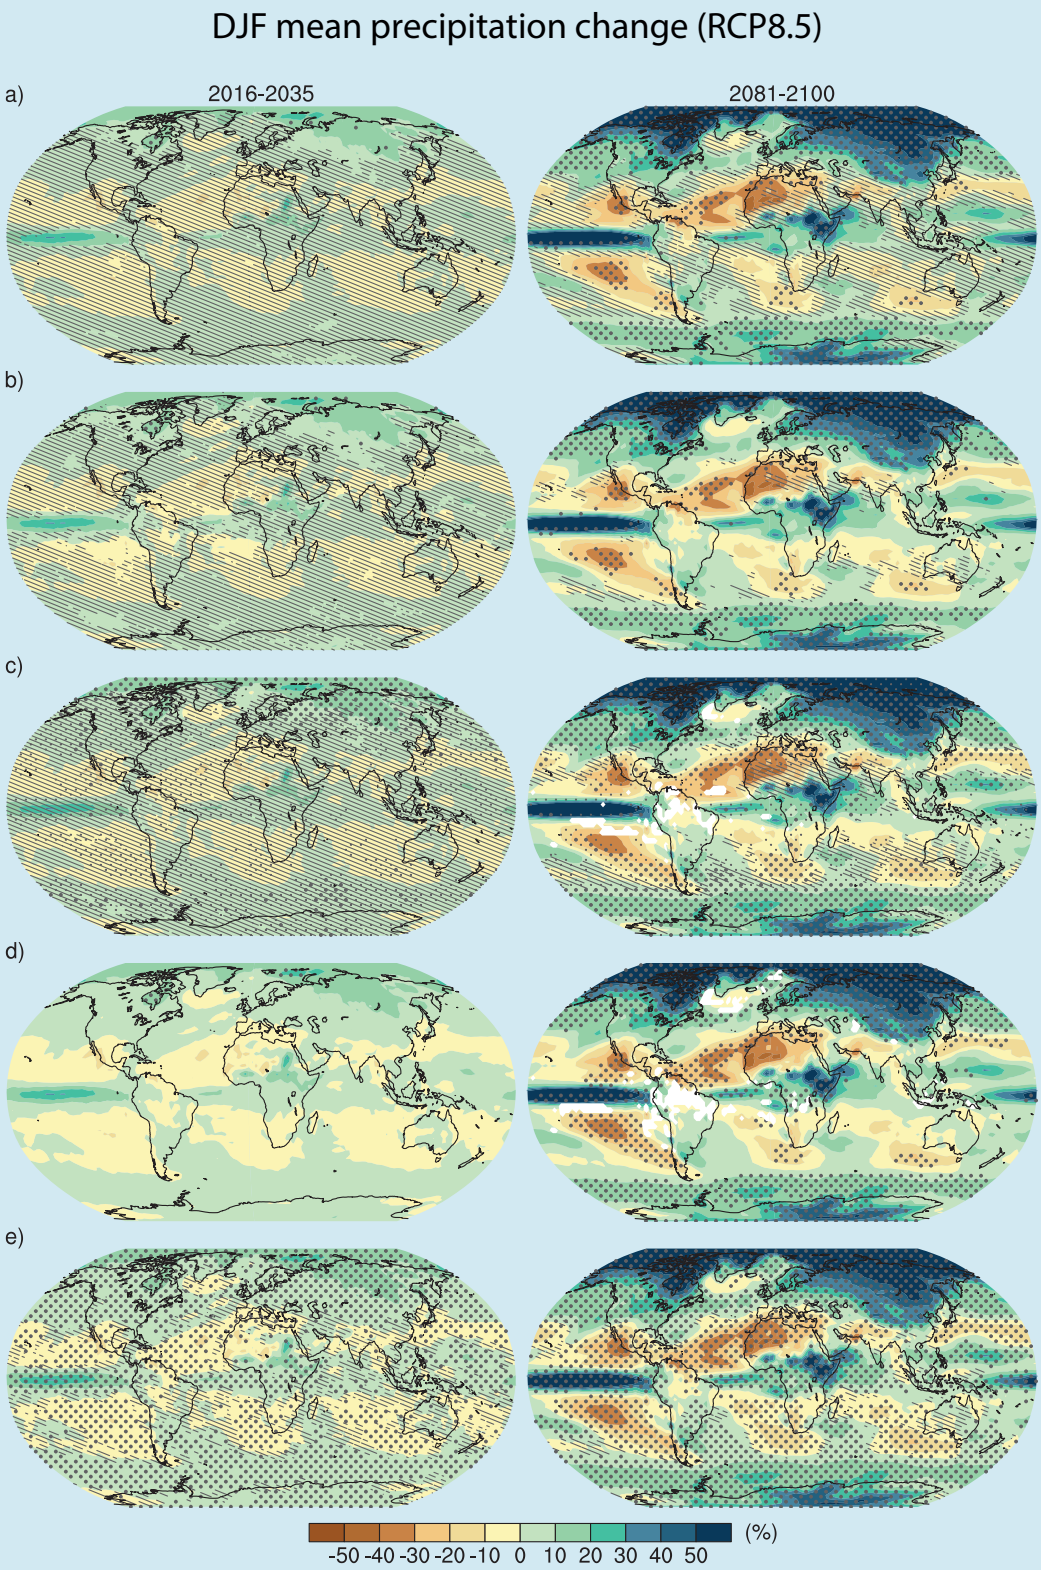
Box 12.1 | Methods to Quantify Model Agreement in Maps

The climate change projections in this report are based on ensembles of climate models. The ensemble mean is a useful quantity to characterize the average response to external forcings, but does not convey any information on the robustness of this response across models, its uncertainty and/or likelihood or its magnitude relative to unforced climate variability. In the IPCC AR4 WGI contribution (IPCC, 2007) several criteria were used to indicate robustness of change, most prominently in Figure SPM.7. In that figure, showing projected precipitation changes, stippling marked regions where at least 90% of the CMIP3 models agreed on the sign of the change. Regions where less than 66% of the models agreed on the sign were masked white. The resulting large white area was often misinterpreted as indicating large uncertainties in the different models' response to external forcings, but recent studies show that, for the most part, the disagreement in sign among models is found where projected changes are small and still within the modelled range of internal variability, that is, where a response to anthropogenic forcings has not yet emerged locally in a statistically significant way (Tebaldi et al., 2011; Power et al., 2012).

A number of methods to indicate model robustness, involving an assessment of the significance of the change when compared to internal variability, have been proposed since AR4. The different methods share the purpose of identifying regions with large, significant or robust changes, regions with small changes, regions where models disagree or a combination of those. They do, however, use different assumptions about the statistical properties of the model ensemble, and therefore different criteria for synthesizing the information from it. Different methods also differ in the way they estimate internal variability. We briefly describe and compare several of these methods here.

Method (a): The default method used in Chapters 11,12 and 14 as well as in the Annex I (hatching only) is shown in Box 12.1, Figure 1a, and is based on relating the climate change signal to internal variability in 20-year means of the models as a reference[3]. Regions where the multi-model mean change exceeds two standard deviations of internal variability and where at least 90% of the models agree on the sign of change are stippled and interpreted as 'large change with high model agreement'. Regions where the model mean is less than one standard deviation of internal variability are hatched and interpreted as 'small signal or low agreement of models'. This can have various reasons: (1) changes in individual models are smaller than internal variability, or (2) although changes in individual models are significant, they disagree about the sign and the multi-model mean change remains small. Using this method, the case where all models scatter widely around zero and the case where all models agree on near zero change therefore are both hatched (e.g., precipitation change over the Amazon region by the end of the 21st century, which the following methods mark as 'inconsistent model response').

Method (b): Method (a) does not distinguish the case where all models agree on no change and the case where, for example, half of the models show a significant increase and half a decrease. The distinction may be relevant for many applications and a modification of method (a) is to restrict hatching to regions where there is high agreement among the models that the change will be 'small', thus eliminating the ambiguous interpretation 'small or low agreement' in (a). In contrast to method (a) where the model mean is compared to variability, this case (b) marks regions where at least 80% of the individual models show a change smaller than two standard deviations of variability with hatching. Grid points where many models show significant change but don't agree are no longer hatched (Box 12.1, Figure 1b).



Method (c): Knutti and Sedláček (2013) define a dimensionless robustness measure, R, which is inspired by the signal-to-noise ratio and the ranked probability skill score. It considers the natural variability and agreement on magnitude and sign of change. A value of $R = 1$ implies perfect model agreement; low or negative values imply poor model agreement (note that by definition R can assume any negative value). Any level of R can be chosen for the stippling. For illustration, in Box 12.1, Figure 1c, regions with $R > 0.8$ are marked with small dots, regions with $R > 0.9$ with larger dots and are interpreted as 'robust large change'. This yields similar results to method (a) for the end of the century, but with some areas of moderate model robustness ($R > 0.8$) already for the near-term projections, even though the signal is still within the noise. Regions where at least 80% of the models individually show no significant change are hatched and interpreted as 'changes unlikely to emerge from variability'[4].There is less hatching in this method than in method (a),

(continued on next page)

[3] The internal variability in this method is estimated using pre-industrial control runs for each of the models which are at least 500 years long. The first 100 years of the pre-industrial are ignored. Variability is calculated for every grid point as the standard deviation of non-overlapping 20-year means, multiplied by the square root of 2 to account for the fact that the variability of a difference in means is of interest. A quadratic fit as a function of time is subtracted from these at every grid point to eliminate model drift. This is by definition the standard deviation of the difference between two independent 20-year averages having the same variance and estimates the variation of that difference that would be expected due to unforced internal variability. The median across all models of that quantity is used.

[4] Variability in methods b–d is estimated from interannual variations in the base period within each model.

Box 12.1 (continued)

Box 12.1, Figure 1 | Projected change in December to February precipitation for 2016–2035 and 2081–2100, relative to 1986–2005 from CMIP5 models. The choice of the variable and time frames is just for illustration of how the different methods compare in cases with low and high signal-to-noise ratio (left and right column, respectively). The colour maps are identical along each column and only stippling and hatching differ on the basis of the different methods. Different methods for stippling and hatching are shown determined (a) from relating the model mean to internal variability, (b) as in (a) but hatching here indicates high agreement for 'small change', (c) by the robustness measure by Knutti and Sedláček (2013), (d) by the method proposed by Tebaldi et al. (2011) and (e) by the method by Power et al. (2012). Detailed technical explanations for each method are given in the text. 39 models are used in all panels.

Box 12.1 (continued)

because it requires 80% of the models to be within variability, not just the model average. Regions where at least 50% of the models show significant change but $R < 0.5$ are masked as white to indicate 'models disagreeing on the projected change projections' (Box 12.1, Figure 1c).

Method (d): Tebaldi et al. (2011) start from IPCC AR4 SPM7 but separate lack of model agreement from lack of signal (Box 12.1, Figure 1e). Grid points are stippled and interpreted as 'robust large change' when more than 50% of the models show significant change and at least 80% of those agree on the sign of change. Grid points where more than 50% of the models show significant change but less than 80% of those agree on the sign of change are masked as white and interpreted as 'unreliable'. The results are again similar to the methods above. No hatching was defined in that method (Box 12.1 Figure 1d). (See also Neelin et al., 2006 for a similar approach applied to a specific regional domain.)

Method (e): Power et al. (2012) identify three distinct regions using various methods in which projections can be very loosely described as either: 'statistically significant', 'small (relative to temporal variability) or zero, but not statistically significant' or 'uncertain'. The emphasis with this approach is to identify robust signals taking the models at face value and to address the questions: (1) What will change? (2) By how much? and (3) What will not change? The underlying consideration here is that statistical testing under the assumption of model independence provides a worthwhile, albeit imperfect, line of evidence that needs to be considered in conjunction with other evidence (e.g., degree of interdependence, ability of models to simulate the past), in order to assess the degree of confidence one has in a projected change.

The examples given here are not exhaustive but illustrate the main ideas. Other methods include simply counting the number of models agreeing on the sign (Christensen et al., 2007), or varying colour hue and saturation to indicate magnitude of change and robustness of change separately (Kaye et al., 2012). In summary, there are a variety of ways to characterize magnitude or significance of change, and agreement between models. There is also a compromise to make between clarity and richness of information. Different methods serve different purposes and a variety of criteria can be justified to highlight specific properties of multi-model ensembles. Clearly only a subset of information regarding robust and uncertain change can be conveyed in a single plot. The methods above convey some important pieces of this information, but obviously more information could be provided if more maps with additional statistics were provided. In fact Annex I provides more explicit information on the range of projected changes evident in the models (e.g., the median, and the upper and lower quartiles). For most of the methods there is a necessity to choose thresholds for the level of agreement that cannot be identified objectively, but could be the result of individual, application-specific evaluations. Note also that all of the above methods measure model agreement in an ensemble of opportunity, and it is impossible to derive a confidence or likelihood statement from the model agreement or model spread alone, without considering consistency with observations, model dependence and the degree to which the relevant processes are understood and reflected in the models (see Section 12.2.3).

The method used by Power et al. (2012) differs from the other methods in that it tests the statistical significance of the ensemble mean rather than a single simulation. As a result, the area where changes are significant increases with an increasing number of models. Already for the period centred on 2025, most of the grid points when using this method show significant change in the ensemble mean whereas in the other methods projections for this time period are classified as changes not exceeding internal variability. The reason is that the former produces a statement about the mean of the distribution being significantly different from zero, equivalent to treating the ensemble as 'truth plus error', that is, assuming that the models are independent and randomly distributed around reality. Methods a–d, on the other hand, use an 'indistinguishable' interpretation, in which each model and reality are drawn from the same distribution. In that case, the stippling and hatching characterize the likelihood of a single member being significant or not, rather than the ensemble mean. There is some debate in the literature on how the multi-model ensembles should be interpreted statistically. This and past IPCC reports treat the model spread as some measure of uncertainty, irrespective of the number of models, which implies an 'indistinguishable' interpretation. For a detailed discussion readers are referred to the literature (Tebaldi and Knutti, 2007; Annan and Hargreaves, 2010; Knutti et al., 2010a, 2010b; Annan and Hargreaves, 2011a; Sanderson and Knutti, 2012).

future projections that are significantly different from straightforward one model–one vote (Knutti, 2010) ensemble results. Therefore, most of the analyses performed for this chapter make use of all available models in the ensembles, with equal weight given to each of them unless otherwise stated.

12.2.4 Joint Projections of Multiple Variables

While many of the key processes relevant to the simulation of single variables are understood, studies are only starting to focus on assessing projections of joint variables, especially when extremes or variability in the individual quantities are of concern. A few studies have addressed projected changes in joint variables, for example, by combining mean temperature and precipitation (Williams et al., 2007; Tebaldi and Lobell, 2008; Tebaldi and Sanso, 2009; Watterson, 2011; Watterson and Whetton, 2011a; Sexton et al., 2012), linking soil moisture, precipitation and temperature mean and variability (Seneviratne et al., 2006; Fischer and Schär, 2009; Koster et al., 2009b, 2009c), combining temperature and humidity (Diffenbaugh et al., 2007; Fischer and Schär, 2010; Willett and Sherwood, 2012), linking summertime temperature and soil moisture to prior winter snowpack (Hall et al., 2008) or linking precipitation change to circulation, moisture and moist static energy budget changes (Neelin et al., 2003; Chou and Neelin, 2004; Chou et al., 2006, 2009). Models may have difficulties simulating all relevant interactions between atmosphere and land surface and the water cycle that determine the joint response, observations to evaluate models are often limited (Seneviratne et al., 2010), and model uncertainties are therefore large (Koster et al., 2006; Boé and Terray, 2008; Notaro, 2008; Fischer et al., 2011). In some cases, correlations between, for example, temperature and precipitation or accumulated precipitation and temperature have found to be too strong in climate models (Trenberth and Shea, 2005; Hirschi et al., 2011). The situation is further complicated by the fact that model biases in one variable affect other variables. The standard method for model projections is to subtract model biases derived from control integrations (assuming that the bias remains constant in a future scenario integration). Several studies note that this may be problematic when a consistent treatment of biases in multiple variables is required (Christensen et al., 2008; Buser et al., 2009), but there is no consensus at this stage for a methodology addressing this problem (Ho et al., 2012). More generally the existence of structural errors in models according to which an unavoidable discrepancy (Rougier, 2007) between their simulations and reality cannot be avoided is relevant here, as well as for univariate projections. In the recent literature an estimate of this discrepancy has been proposed through the use of MMEs, using each model in turn as a surrogate for reality, and measuring the distance between it and the other models of the ensemble. Some summary statistic of these measures is then used to estimate the distance between models and the real world (Sexton and Murphy, 2012; Sexton et al., 2012; Sanderson, 2013). Statistical frameworks to deal with multivariate projections are challenging even for just two variables, as they have to address a trade-off between modelling the joint behavior at scales that are relevant for impacts—that is, fine spatial and temporal scales, often requiring complex spatio-temporal models—and maintaining computational feasibility. In one instance (Tebaldi and Sanso, 2009) scales were investigated at the seasonal and sub-continental level, and projections of the forced response of temperature and precipitation at those scales did not show significant correlations, likely because of the heterogeneity of the relation between the variables within those large averaged regions and seasons. In Sexton et al. (2012) the spatial scale focussed on regions of Great Britain and correlation emerged as more significant, for example, between summer temperatures and precipitation amounts. Fischer and Knutti (2013) estimated strong relationships between variables making up impact relevant indices (e.g., temperature and humidity) and showed how in some cases, uncertainties across models are larger for a combined variable than if the uncertainties in the individual underlying variables were treated independently (e.g., wildfires), whereas in other cases the uncertainties in the combined variables are smaller than in the individual ones (e.g., heat stress for humans).

Even while recognizing the need for joint multivariate projections, the above limitations at this stage prevent a quantitative assessment for most cases. A few robust qualitative relationships nonetheless emerge from the literature and these are assessed, where appropriate, in the rest of the chapter. For applications that are sensitive to relationships between variables, but still choose to use the multi-model framework to determine possible ranges for projections, sampling from univariate ranges may lead to unrealistic results when significant correlations exist. IPCC assessments often show model averages as best estimates, but such averages can underestimate spatial variability, and more in general they neither represent any of the actual model states (Knutti et al., 2010a) nor do they necessarily represent the joint best estimate in a multivariate sense. Impact studies usually need temporally and spatially coherent multivariate input from climate model simulations. In those cases, using each climate model output individually and feeding it into the impact model, rather than trying to summarise a multivariate distribution from the MME and sample from it, is likely to be more consistent, assuming that the climate model itself correctly captures the spatial covariance, the temporal co-evolution and the relevant feedbacks.

12.3 Projected Changes in Forcing Agents, Including Emissions and Concentrations

The experiments that form the basis of global future projections discussed in this chapter are extensions of the simulations of the observational record discussed in Chapters 9 and 10. The scenarios assessed in AR5, introduced in Chapter 1, include four new scenarios designed to explore a wide range of future climate characterized by representative trajectories of well-mixed greenhouse gas (WMGHG) concentrations and other anthropogenic forcing agents. These are described further in Section 12.3.1. The implementation of forcing agents in model projections, including natural and anthropogenic aerosols, ozone and land use change are discussed in Section 12.3.2, with a strong focus on CMIP5 experiments. Global mean emissions, concentrations and RFs applicable to the historical record simulations assessed in Chapters 8, 9 and 10, and the future scenario simulations assessed here, are listed in Annex II. Global mean RF for the 21st century consistent with these scenarios, derived from CMIP5 and other climate model studies, is discussed in Section 12.3.3.

12.3.1 Description of Scenarios

Long-term climate change projections reflect how human activities or natural effects could alter the climate over decades and centuries. In this context, defined scenarios are important, as using specific time series of emissions, land use, atmospheric concentrations or RF across multiple models allows for coherent climate model intercomparisons and synthesis. Some scenarios present a simple stylized future (not accompanied by a socioeconomic storyline) and are used for process understanding. More comprehensive scenarios are produced by Integrated Assessment Models (IAMs) as internally consistent sets of emissions and socioeconomic assumptions (e.g., regarding population and socioeconomic development) with the aim of presenting several plausible future worlds (see Section 1.5.2 and Box 1.1). In general it is these scenarios that are used for policy relevant climate change, impact, adaptation and mitigation analysis. It is beyond the scope of this report to consider the full range of currently published scenarios and their implications for mitigation policy and climate targets—that is covered by the Working Group III contribution to the AR5. Here, we focus on the RCP scenarios used within the CMIP5 intercomparison exercise (Taylor et al. 2012) along with the SRES scenarios (IPCC, 2000) developed for the IPCC Third Assessment Report (TAR) but still widely used by the climate community.

12.3.1.1 Stylized Concentration Scenarios

A 1% per annum compound increase of atmospheric CO_2 concentration until a doubling or a quadrupling of its initial value has been widely used since the second phase of CMIP (Meehl et al., 2000) and the Second Assessment Report (Kattenberg et al., 1996). This stylized scenario is a useful benchmark for comparing coupled model climate sensitivity, climate feedback and transient climate response, but is not used directly for future projections. The exponential increase of CO_2 concentration induces approximately a linear increase in RF due to a 'saturation effect' of the strong absorbing bands (Augustsson and Ramanathan, 1977; Hansen et al., 1988; Myhre et al., 1998). Thus, a linear ramp function in forcing results from these stylized pathways, adding to their suitability for comparative diagnostics of the models' climate feedbacks and inertia. The CMIP5 intercomparison project again includes such a stylized pathway, in which the CO_2 concentration reaches twice the initial concentration after 70 years and four times the initial concentration after 140 years. The corresponding RFs are 3.7 W m^{-2} (Ramaswamy et al., 2001) and 7.4 W m^{-2} respectively with a range of ±20% accounting for uncertainties in radiative transfer calculations and rapid adjustments (see Section 8.3.2.1), placing them within the range of the RFs at the end of the 21st century for the future scenarios presented below. The CMIP5 project also includes a second stylized experiment in which the CO_2 concentration is quadrupled instantaneously, which allows a distinction between effective RFs and longer-term climate feedbacks (Gregory et al., 2004).

12.3.1.2 The Socioeconomic Driven Scenarios from the Special Report on Emission Scenarios

The climate change projections undertaken as part of CMIP3 and discussed in AR4 were based primarily on the SRES A2, A1B and B1 scenarios (IPCC, 2000). These scenarios were developed using IAMs and resulted from specific socioeconomic scenarios, that is, from storylines about future demographic and economic development, regionalization, energy production and use, technology, agriculture, forestry, and land use. All SRES scenarios assumed that no climate mitigation policy would be undertaken. Based on these SRES scenarios, global climate models were then forced with corresponding WMGHG and aerosol concentrations, although the degree to which models implemented these forcings differed (Meehl et al., 2007b, Table 10.1). The resulting climate projections, together with the socioeconomic scenarios on which they are based, have been widely used in further analysis by the impact, adaptation and vulnerability research communities.

12.3.1.3 The New Concentration Driven Representative Concentration Pathway Scenarios, and Their Extensions

As introduced in Box 1.1 and mentioned in Section 12.1, a new parallel process for scenario development was proposed in order to facilitate the interactions between the scientific communities working on climate change, adaptation and mitigation (Hibbard et al., 2007; Moss et al., 2008, 2010; van Vuuren et al., 2011). These new scenarios, Representative Concentration Pathways, are referred to as pathways in order to emphasize that they are not definitive scenarios, but rather internally consistent sets of time-dependent forcing projections that could potentially be realized with more than one underlying socioeconomic scenario. The primary products of the RCPs are concentrations but they also provide gas emissions. They are representative in that they are one of several different scenarios, sampling the full range of published scenarios (including mitigation scenarios) at the time they were defined, that have similar RF and emissions characteristics. They are identified by the approximate value of the RF (in W m^{-2}) at 2100 or at stabilization after 2100 in their extensions, relative to pre-industrial (Moss et al., 2008; Meinshausen et al., 2011c). RCP2.6 (the lowest of the four, also referred to as RCP3-PD) peaks at 3.0 W m^{-2} and then declines to 2.6 W m^{-2} in 2100, RCP4.5 (medium-low) and RCP6.0 (medium-high) stabilize after 2100 at 4.2 and 6.0 W m^{-2} respectively, while RCP8.5 (highest) reaches 8.3 W m^{-2} in 2100 on a rising trajectory (see also Figure 12.3a which takes into account the efficacies of the various anthropogenic forcings). The primary objective of these scenarios is to provide all the input variables necessary to run comprehensive climate models in order to reach a target RF (Figure 12.2). These scenarios were developed using IAMs that provide the time evolution of a large ensemble of anthropogenic forcings (concentration and emission of gas and aerosols, land use changes, etc.) and their individual RF values (Moss et al., 2008, 2010; van Vuuren et al., 2011). Note that due to the substantial uncertainties in RF, these forcing values should be understood as comparative 'labels', not as exact definitions of the forcing that is effective in climate models. This is because concentrations or emissions, rather than the RF itself, are prescribed in the CMIP5 climate model runs. The forcing as manifested in climate models is discussed in Section 12.3.3.

Various steps were necessary to turn the selected 'raw' RCP scenarios from the IAMs into data sets usable by the climate modelling community. First, harmonization with historical data was performed for emissions of reactive gases and aerosols (Lamarque et al., 2010; Granier et al., 2011; Smith et al., 2011), land use (Hurtt et al., 2011), and for GHG emissions and concentrations (Meinshausen et al., 2011c). Then

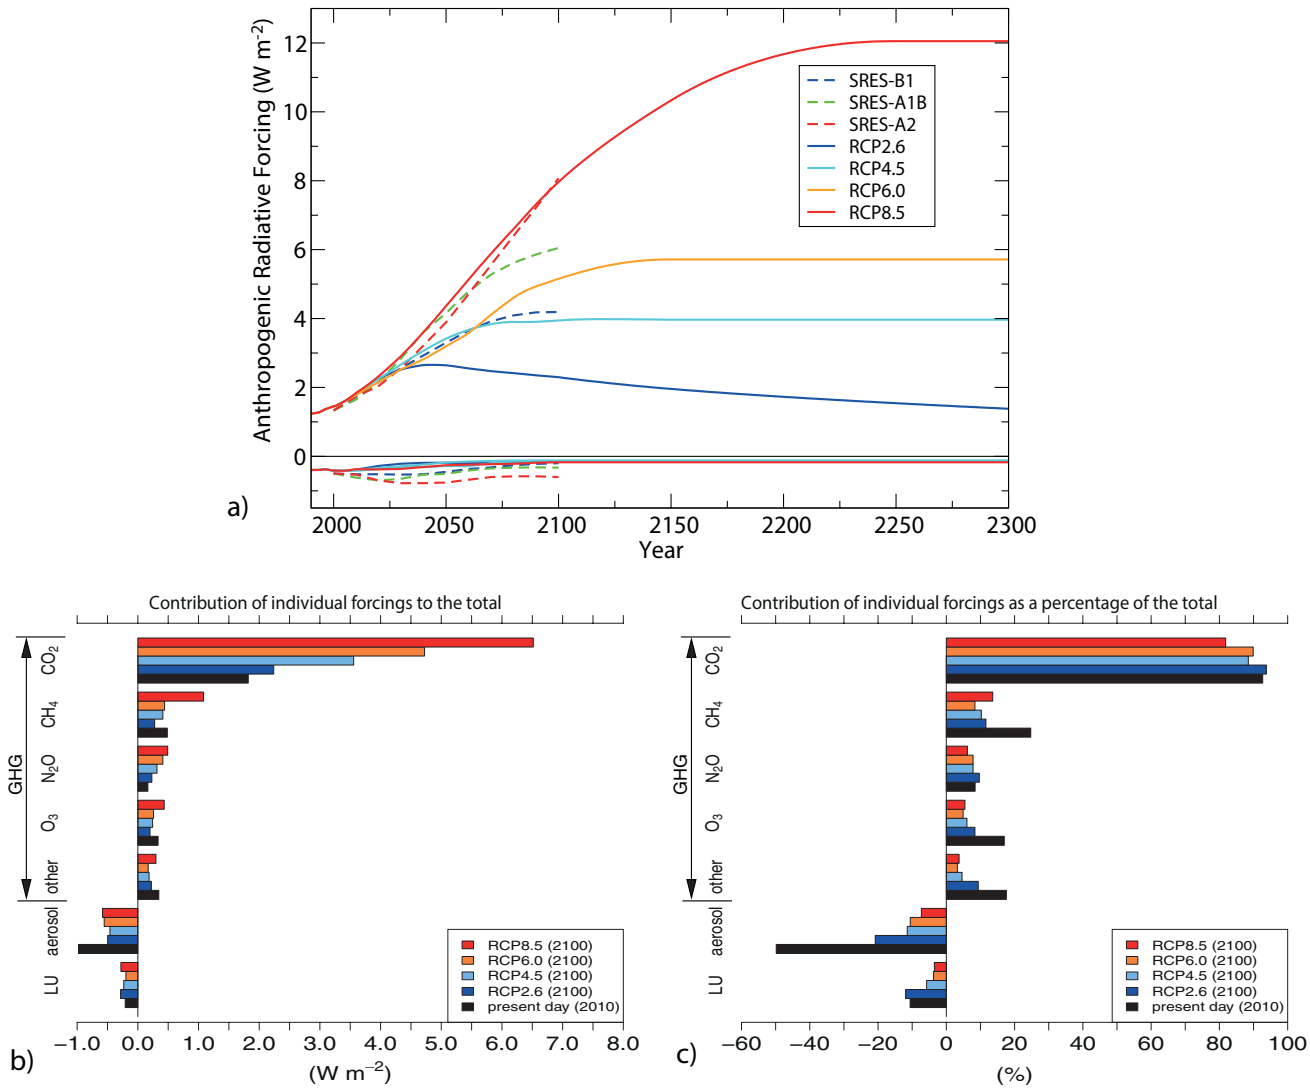


Figure 12.3 | (a) Time evolution of the total anthropogenic (positive) and anthropogenic aerosol (negative) radiative forcing (RF) relative to pre-industrial (about 1765) between 2000 and 2300 for RCP scenarios and their extensions (continuous lines), and SRES scenarios (dashed lines) as computed by the Integrated Assessment Models (IAMs) used to develop those scenarios. The four RCP scenarios used in CMIP5 are: RCP2.6 (dark blue), RCP4.5 (light blue), RCP6.0 (orange) and RCP8.5 (red). The three SRES scenarios used in CMIP3 are: B1 (blue, dashed), A1B (green, dashed) and A2 (red, dashed). Positive values correspond to the total anthropogenic RF. Negative values correspond to the forcing from all anthropogenic aerosol–radiation interactions (i.e., direct effects only). The total RF of the SRES and RCP families of scenarios differs in 2000 because the number of forcings represented and our knowledge about them have changed since the TAR. The total RF of the RCP family is computed taking into account the efficacy of the various forcings (Meinshausen et al., 2011a). (b) Contribution of the individual anthropogenic forcings to the total RF in year 2100 for the four RCP scenarios and at present day (year 2010). The individual forcings are gathered into seven groups: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), ozone (O_3), other greenhouse gases, aerosol (all effects unlike in (a), i.e., aerosol–radiation and aerosol–cloud interactions, aerosol deposition on snow) and land use (LU). (c) As in (b), but the individual forcings are relative to the total RF (i.e., RF_x/RF_{tot}, in %, with RF_x individual RFs and RF_{tot} total RF). Note that the RFs in (b) and (c) are not efficacy adjusted, unlike in (a). The values shown in (a) are summarized in Table AII.6.8. The values shown in (b) and (c) have been directly extracted from data files (hosted at http://tntcat.iiasa.ac.at:8787/RcpDb/) compiled by the four modelling teams that developed the RCP scenarios and are summarized in Tables AII.6.1 to AII.6.3 for CO_2, CH_4 and N_2O respectively.

atmospheric chemistry runs were performed to estimate ozone and aerosol distributions (Lamarque et al., 2011). Finally, a single carbon cycle model with a representation of carbon–climate feedbacks was used in order to provide consistent values of CO_2 concentration for the CO_2 emission provided by a different IAM for each of the scenarios. This methodology was used to produce consistent data sets across scenarios but does not provide uncertainty estimates for them. After these processing steps, the final RCP data sets comprise land use data, harmonized GHG emissions and concentrations, gridded reactive gas and aerosol emissions, as well as ozone and aerosol abundance fields. These data are used as forcings in individual climate models. The number and type of forcings included primarily depend on the experiment. For instance, while the CO_2 concentration is prescribed in most experiments, CO_2 emissions are prescribed in some others (see Box 6.4 and Section 12.3.2.1). Which of these forcings are included in individual CMIP5 models, and variations in their implementation, is described in Section 12.3.2.2.

During this development process, the total RF and the RF of individual forcing agents have been estimated by the IAMs and made available via the RCP database (Meinshausen et al., 2011c). Each individual anthropogenic forcing varies from one scenario to another. They have

been aggregated into a few groups in Figure 12.3b and c. The total anthropogenic RF estimated by the IAMs in 2010 is about 0.15 W m^{-2} lower than Chapter 8's best estimate of ERF in 2010 (2.2 W m^{-2}), the difference arising from a revision of the RF due to aerosols and land use in the current assessment compared to AR4. All the other individual forcings are consistent to within 0.02 W m^{-2}. The change in CO_2 concentration is the main cause of difference in the total RF among the scenarios (Figure 12.3b). The relative contribution[5] of CO_2 to the total anthropogenic forcing is currently (year 2010) about 80 to 90% and does not vary much across the scenarios (Figure 12.3c), as was also the case for SRES scenarios (Ramaswamy et al., 2001). Aerosols have a large negative contribution to the total forcing (about –40 to –50% in 2010), but this contribution decreases (in both absolute and relative terms) in the future for all the RCPs scenarios. This means that while anthropogenic aerosols have had a cooling effect in the past, their decrease in all RCP scenarios relative to current levels is expected to have a net warming effect in the future (Levy II et al., 2013; see also Figure 8.20). The 21st century decrease in the magnitude of future aerosol forcing was not as large and as rapid in the SRES scenarios (Figure 12.3a). However, even in the SRES scenarios, aerosol effects were expected to have a diminishing role in the future compared to GHG forcings, mainly because of the accumulation of GHG in the atmosphere (Dufresne et al., 2005). Other forcings do not change much in the future, except CH_4 which increases in the RCP8.5 scenario. Note that the estimates of all of these individual RFs are subject to many uncertainties (see Sections 7.5, 8.5 and 11.3.6). In this section and in Table AII.6.8, the RF values for RCP scenarios are derived from published equivalent-CO_2 (CO_2eq) concentration data that aggregates all anthropogenic forcings including GHGs and aerosols. The conversion to RF uses the formula: $RF = 3.71/\ln(2) \cdot \ln(CO_2eq/278)$ W m^{-2}, where CO_2eq is in ppmv.

The four RCPs (Meinshausen et al., 2011c) are based on IAMs up to the end of the 21st century only. In order to investigate longer-term climate change implications, these RCPs were also extended until 2300. The extensions, formally named Extended Concentration Pathways (ECPs) but often simply referred to as RCP extensions, use simple assumptions about GHG and aerosol emissions and concentrations beyond 2100 (such as stabilization or steady decline) and were designed as hypothetical 'what-if' scenarios, not as an outcome of an IAM assuming socioeconomic considerations beyond 2100 (Meinshausen et al., 2011c) (see Box 1.1). In order to continue to investigate a broad range of possible climate futures, RCP2.6 assumes small constant net negative emissions after 2100 and RCP8.5 assumes stabilization with high emissions between 2100 and 2150, then a linear decrease until 2250. The two middle RCPs aim for a smooth stabilization of concentrations by 2150. RCP8.5 stabilizes concentrations only by 2250, with CO_2 concentrations of approximately 2000 ppmv, nearly seven times the pre-industrial level. As RCP2.6 implies net negative CO_2 emissions after around 2070 and throughout the extension, CO_2 concentrations slowly reduce towards 360 ppmv by 2300.

12.3.1.4 Comparison of Special Report on Emission Scenarios and Representative Concentration Pathway Scenarios

The four RCP scenarios used in CMIP5 lead to RF values that range from 2.3 to 8.0 W m^{-2} at 2100, a wider range than that of the three SRES scenarios used in CMIP3 which vary from 4.2 to 8.1 W m^{-2} at 2100 (see Table AII.6.8 and Figure 12.3). The SRES scenarios do not assume any policy to control climate change, unlike the RCP scenarios. The RF of RCP2.6 is hence lower by 1.9 W m^{-2} than the three SRES scenarios and very close to the ENSEMBLES E1 scenario (Johns et al., 2011). RCP4.5 and SRES B1 have similar RF at 2100, and comparable time evolution (within 0.2 W m^{-2}). The RF of SRES A2 is lower than RCP8.5 throughout the 21st century, mainly due to a faster decline in the radiative effect of aerosols in RCP8.5 than SRES A2, but they converge to within 0.1 W m^{-2} at 2100. RCP6.0 lies in between SRES B1 and SRES A1B. Results obtained with one General Circulation Model (GCM) (Dufresne et al., 2013) and with a reduced-complexity model (Rogelj et al., 2012) confirm that the differences in temperature responses are consistent with the differences in RFs estimates. RCP2.6, which assumes strong mitigation action, yields a smaller temperature increase than any SRES scenario. The temperature increase with the RCP4.5 and SRES B1 scenarios are close and the temperature increase is larger with RCP8.5 than with SRES A2. The spread of projected global mean temperature for the RCP scenarios (Section 12.4.1) is considerably larger (at both the high and low response ends) than for the three SRES scenarios used in CMIP3 (B1, A1B and A2) as a direct consequence of the larger range of RF across the RCP scenarios compared to that across the three SRES scenarios (see analysis of SRES versus RCP global temperature projections in Section 12.4.9 and Figure 12.40).

12.3.2 Implementation of Forcings in Coupled Model Intercomparison Project Phase 5 Experiments

The CMIP5 experimental protocol for long-term transient climate experiments prescribes a common basis for a comprehensive set of anthropogenic forcing agents acting as boundary conditions in three experimental phases—historical, RCPs and ECPs (Taylor et al., 2012). To permit common implementations of this set of forcing agents in CMIP5 models, self-consistent forcing data time series have been computed and provided to participating models (see Sections 9.3.2.2 and 12.3.1.3) comprising emissions or concentrations of GHGs and related compounds, ozone and atmospheric aerosols and their chemical precursors, and land use change.

The forcing agents implemented in Atmosphere–Ocean General Circulation Models (AOGCMs) and ESMs used to make long-term climate projections in CMIP5 are summarized in Table 12.1. The number of CMIP5 models listed here is about double the number of CMIP3 models listed in Table 10.1 of AR4 (Meehl et al., 2007b).

Natural forcings (arising from solar variability and aerosol emissions via volcanic activity) are also specified elements in the CMIP5 experimental protocol, but their future time evolutions are not prescribed

[5] The range of the relative contribution of CO_2 and aerosols to the total anthropogenic forcing is derived here from the RF values given by the IAMs and the best estimate assessed in Chapter 8.

Table 12.1 | Radiative forcing agents in the CMIP5 multi-model global climate projections. See Table 9.A.1 for descriptions of the models and main model references. Earth System Models (ESMs) are highlighted in bold. Numeric superscripts indicate model-specific references that document forcing implementations. Forcing agents are mostly implemented in close conformance with standard prescriptions (Taylor et al., 2012) and recommended data sets (Lamarque et al., 2010; Cionni et al., 2011; Lamarque et al., 2011; Meinshausen et al., 2011c) provided for CMIP5. Variations in forcing implementations are highlighted with superscripts and expanded in the table footnotes. Entries mean: n.a.: Forcing agent is not included in either the historical or future scenario simulations; Y: Forcing agent included (via prescribed concentrations, distributions or time series data); E: Concentrations of forcing agent calculated interactively driven by prescribed emissions or precursor emissions; Es: Concentrations of forcing agent calculated interactively constrained by prescribed surface concentrations. For a more detailed classification of ozone chemistry and ozone forcing implementations in CMIP5 models see Eyring et al. (2013).

Table 12.1 (continued)

Additional notes:

ce Separate entries for CO_2 denote 'concentration-driven' and 'emissions-driven' experiments as indicated.

ac 'Cloud albedo effect' and 'Cloud lifetime effect' are classical terms (as used in AR4) to describe indirect effects of radiative forcing associated with aerosols. They relate to the revised terminologies defined in Chapter 7 and used in AR5: 'Radiative forcing from aerosol–cloud interactions (RFaci)' and 'Effective radiative forcing from aerosol–cloud interactions (ERFaci)'. RFaci equates to cloud albedo effect, while ERFaci is the effective forcing resulting from cloud albedo effect plus cloud lifetime effect, including all rapid adjustments to cloud lifetime and thermodynamics (Section 7.1.3, Figure 7.3).

p Physiological forcing effect of CO_2 via plant stomatal response and evapotranspiration (Betts et al., 2007) included.

rc Separate entries denote different treatments used for radiation and chemistry respectively.

hf Separate entries denote treatment for historical and future (RCPs) respectively.

a Three-dimensional tropospheric ozone, stratospheric ozone, methane, and/or aerosol distributions specified as monthly 10-year mean concentrations, computed off-line using CAM-Chem – a modified version of CAM3.5 with interactive chemistry – driven with specified emissions for the historical period (Lamarque et al., 2010) and RCPs (Lamarque et al., 2011) with sea surface temperature and sea ice boundary conditions based on CCSM3's projections for the closest corresponding AR4 scenarios.

b Ozone prescribed using the original or slightly modified IGAC/SPARC ozone data set (Cionni et al., 2011); in some models this data set is modified to add a future solar cycle and in some models tropospheric ozone is zonally averaged.

c Linearized 2D ozone chemistry scheme (Cariolle and Teyssedre, 2007) including transport and photochemistry, reactive to stratospheric chlorine concentrations but not tropospheric chemical emissions.

d Ozone prescribed using the data set described in Hansen et al. (2007), with historical tropospheric ozone being calculated by a CCM and stratospheric ozone taken from Randel and Wu (2007) in the past. Tropospheric ozone is held constant from 1990 onwards, while stratospheric ozone is constant from 1997 to 2003 and then returned linearly to its 1979 value over the period 2004 to 2050.

e For IPSL-CM5 model versions, ozone and aerosol concentrations are calculated semi-offline with the atmospheric general circulation model including interactive chemistry and aerosol, following the four RCPs in the future (Dufresne et al., 2013; Szopa et al., 2013). The same aerosol concentration fields (but not ozone) are also prescribed for the CNRM-CM5 model.

f Ozone concentrations computed off-line by Kawase et al. (2011) using a CCM forced with CMIP5 emissions.

g Ozone concentrations computed off-line by Sudo et al. (2003) for the historical period and Kawase et al. (2011) for the future.

h Time dependent climatology based on simulations and observations; aerosols are distinguished only with respect to coarse and fine mode, and anthropogenic and natural origins, not with respect to composition.

op Separate entries denote different ozone chemistry precursors.

so RFaci from sulphate aerosol only.

st Separate entries denote stratosphere and troposphere respectively.

ic Radiative effects of aerosols on ice clouds are represented.

pd Prognostic or diagnostic scheme for dust/sea salt aerosol with emissions/concentrations determined by the model state rather than externally prescribed.

fx Fixed prescribed climatology of dust/sea salt aerosol concentrations with no year-to-year variability.

v0 Explosive volcanic aerosol returns rapidly in future to zero (or near-zero) background, like that in the pre-industrial control experiment.

v1 Explosive volcanic aerosol returns rapidly in future to constant (average volcano) background, the same as in the pre-industrial control experiment.

v2 Explosive volcanic aerosol returns slowly in future (over several decades) to constant (average volcano) background like that in the pre-industrial control experiment.

v3 Explosive volcanic aerosol returns rapidly in future to near-zero background, below that in the pre-industrial control experiment.

v4 Explosive volcanic aerosol set to zero in future, but constant (average volcano) background in the pre-industrial control experiment.

v5 Explosive volcanic aerosol returns slowly in future (over several decades) to constant (average volcano) background, but zero background in the pre-industrial control experiment.

cr Land use change represented via crop change only.

or Realistic time-varying orbital parameters for solar forcing (in historical period only for GISS-E2).

very precisely. A repeated 11-year cycle for total solar irradiance (Lean and Rind, 2009) is suggested for future projections but the periodicity is not specified precisely as solar cycles vary in length. Some models include the effect of orbital variations as well, but most do not. For volcanic eruptions, no specific CMIP5 prescription is given for future emissions or concentration data, the general recommendation being that volcanic aerosols should either be omitted entirely both from the control experiment and future projections or the same background volcanic aerosols should be prescribed in both. This provides a consistent framework for model intercomparison given a lack of knowledge of when future large eruptions will occur. In general models have adhered to this guidance, but there are variations in the background volcanic aerosol levels chosen (zero or an average volcano background in general) and some cases, for example, Australian Community Climate and Earth System Simulator (ACCESS)1.0 and ACCESS1.3 (Dix et al., 2013), where the background volcanic aerosol in future differs significantly from that in the control experiment, with a small effect on future RF.

For the other natural aerosols (dust, sea-salt, etc.), no emission or concentration data are recommended. The emissions are potentially computed interactively by the models themselves and may change with climate, or prescribed from separate model simulations carried out in the implementation of CMIP5 experiments, or simply held constant. Natural aerosols (mineral dust and sea salt) are in a few cases prescribed with no year-to-year variation (giving no transient forcing effect), in some cases prescribed from data sets computed off-line as described above, and in other cases calculated interactively via prognostic or diagnostic calculations. The degree to which natural aerosol emissions are interactive is effectively greater in some such models than others, however, as mineral dust emissions are more constrained when land vegetation cover is specified (e.g., as in Commonwealth Scientific and Industrial Research Organisation (CSIRO)-Mk3.6.0) (Rotstayn et al., 2012) than when vegetation is allowed to evolve dynamically (e.g., as in Hadley Centre new Global Environmental Model 2-ES (HadGEM2-ES)) (Jones et al., 2011) (Table 9.A.1).

12.3.2.1 'Emissions-Driven' versus 'Concentration Driven' Experiments

A novel feature within the CMIP5 experimental design is that experiments with prescribed anthropogenic emissions are included in addition to classical experiments with prescribed concentration pathways for WMGHGs (Taylor et al., 2012). The essential features of these two classes of experiment are described in Box 6.4. The CMIP5 protocol includes experiments in which 'ESMs' (models possessing at least a carbon cycle, allowing for interactive calculation of atmospheric CO_2 or compatible emissions) and AOGCMs (that do not possess such an interactive carbon cycle) are both forced with WMGHG concentration pathways to derive a range of climate responses consistent with those pathways from the two types of model. The range of climate responses including climate–carbon cycle feedbacks can additionally be explored in ESMs driven with emissions rather than concentrations, analogous to Coupled Climate Carbon Cycle Model Intercomparison Project (C^4MIP) experiments (Friedlingstein et al., 2006)—see Box 6.4. Results from the two types of experiment cannot be compared directly, but they provide complementary information. Uncertainties in the forward climate response driven with specified emissions or concentrations can be derived from all participating models, while concentration-driven ESM experiments also permit a policy-relevant diagnosis of the range of anthropogenic carbon emissions compatible with the imposed concentration pathways (Hibbard et al., 2007; Moss et al., 2010).

WMGHG forcing implementations in CMIP5 concentration-driven experiments conform closely in almost all cases to the standard protocol (Table 12.1; CO_2, CH_4, N_2O, chlorofluorocarbons (CFCs)), imposing an effective control over the RF due to WMGHGs across the multi-model ensemble, apart from the model spread arising from radiative transfer codes (Collins et al., 2006b; Meehl et al., 2007b). The ability of ESMs to determine their own WMGHG concentrations in emissions-driven experiments means that RF due to WMGHGs is less tightly controlled in such experiments. Even in concentration-driven experiments, many models implement some emissions-driven forcing agents (more often aerosols, but also ozone in some cases), leading to a potentially greater spread in both the concentrations and hence RF of those emissions-driven agents.

12.3.2.2 Variations Between Model Forcing Implementations

Apart from the distinction between concentration-driven and emissions-driven protocols, a number of variations are present in the implementation of forcing agents listed in Table 12.1, which generally arise due to constraining characteristics of the model formulations, various computational efficiency considerations or local implementation decisions. In a number of models, off-line modelling using an aerosol chemistry climate model has been used to convert emissions into concentrations compatible with the specific model formulation or characteristics. As a result, although detailed prescriptions are given for the forcing agents in CMIP5 experiments in emissions terms, individual modelling approaches lead to considerable variations in their implementations and consequential RFs. This was also the case in the ENSEMBLES multi-model projections, in which similar forcing agents to CMIP5 models were applied but again with variations in the implementation of aerosol, ozone and land use forcings, prescribing the SRES A1B and E1 scenarios in a concentration-driven protocol (Johns et al., 2011) akin to the CMIP5 protocol.

Methane, nitrous oxide and CFCs (typically with some aggregation of the multiple gases) are generally prescribed in CMIP5 models as well-mixed concentrations following the forcing data time series provided for the given scenarios. In a number of models (CESM1(WACCM), GFDL-CM3, GISS-E2-p2, GISS-E2-p3, HadGEM2-ES and MRI-ESM1) the three-dimensional concentrations in the atmosphere of some species evolve interactively driven by the full emissions/sinks cycle (in some cases constrained by prescribed concentrations at the surface, e.g., HadGEM2-ES for methane). In cases where the full emissions/sinks cycle is modelled, the radiation scheme is usually passed the time-varying 3-D concentrations, but some models prescribe different concentrations for the purpose of radiation.

Eyring et al. (2013) document, in greater detail than Table 12.1, the implementations of tropospheric and stratospheric ozone in CMIP5 models, including their ozone chemistry schemes and modifications applied to reference data sets in models driven by concentrations. In

most models that prescribe ozone, concentrations are based on the original or slightly modified CMIP5 standard ozone data set computed as part of the International Global Atmospheric Chemistry/Stratospheric Processes and their Role in Climate (IGAC/SPARC) activity (Cionni et al., 2011). In the stratosphere, this data set is based on observations of the past (Randel and Wu, 2007) continued into the future with the multi-model mean of 13 chemistry–climate models (CCMs) projections following the SRES A1B (IPCC, 2000) and SRES A1 adjusted halogen scenario (WMO, 2007). The stratospheric zonal mean ozone field is merged with a 3-D tropospheric ozone time series generated as the mean of two CCMs (Goddard Institute of Space Studies-Physical Understanding of Composition-Climate Interactions and Impacts (GISS-PUCCINI), Shindell et al., 2006; CAM3.5, Lamarque et al., 2010) in the past and continued by one CCM (CAM3.5) in the future. Some CMIP5 models (MIROC-ESM, MIROC4h, MIROC5 and GISS-E2-p1) prescribe ozone concentrations using different data sets but again following just one GHG scenario in the future for the projection of stratospheric ozone. In other models (e.g., Institut Pierre Simon Laplace (IPSL)-CM5, CCSM4) ozone is again prescribed, but supplied as concentrations from off-line computations using a related CCM. Some models determine ozone interactively from specified emissions via on-line atmospheric chemistry (CESM1(FASTCHEM), CESM1(WACCM), CNRM-CM5, GFDL-CM3, GISS-E2-p2, GISS-E2-p3, MIROC-ESM-CHEM, MRI-ESM1; and HadGEM2-ES for tropospheric ozone only). Computing ozone concentrations interactively allows the fast coupling between chemistry and climate to be captured, but modelling of chemistry processes is sometimes simplified (CNRM-CM5, CESM(FASTCHEM)) in comparison with full complexity CCMs to reduce the computational cost. Compared to CMIP3, in which all models prescribed ozone and around half of them used a fixed ozone climatology, this leads to substantial improvement to ozone forcings in CMIP5, although differences remain among the models with interactive chemistry.

For atmospheric aerosols, either aerosol precursor emissions-driven or concentration-driven forcings are applied depending on individual model characteristics (see Sections 7.3 and 7.4 for an assessment of aerosols processes including aerosol–radiation and aerosol–cloud interactions). A larger fraction of models in CMIP5 than CMIP3 prescribe aerosol precursor emissions rather than concentrations. Many still prescribe concentrations pre-computed either using a directly related aerosol CCM or from output of another, complex, emissions-driven aerosol chemistry model within the CMIP5 process. As for ozone, aerosol concentrations provided from off-line simulations help to reduce the computational burden of the projections themselves. For several of the concentration-driven models (CCSM4, IPSL-CM5A variants, MPI-ESM-LR, MPI-ESM-MR), additional emissions-driven simulations have been undertaken to tailor the prescribed concentrations closely to the model's individual aerosol–climate characteristics. Lamarque et al. (2010, 2011) provided the recommended CMIP5 aerosols data set which has been used in several of the models driven by concentrations. Compared with the CMIP3 models, a much larger fraction of CMIP5 models now incorporate black and organic carbon aerosol forcings. Also, a larger fraction of CMIP5 than CMIP3 models now includes a range of processes that combine in the effective RF from aerosol–cloud interactions (ERFaci; see Section 7.1.3 and Figure 7.3). Previously such processes were generally termed aerosol indirect effects, usually separated into cloud albedo (or first indirect) effect and cloud lifetime (or second indirect) effect. Many CMIP5 models only include the interaction between sulphate aerosol and cloud, and the majority of them only model the effect of aerosols on cloud albedo rather than cloud lifetime (Table 12.1). No CMIP5 models represent urban aerosol pollution explicitly so that is not listed in Table 12.1 (see Section 11.3.5.2 for discussion of future air quality). Only one model (GISS-E2) explicitly includes nitrate aerosol as a separate forcing, though it is also included within the total aerosol mixture in the Max Planck Institute-Earth System Model (MPI-ESM) model versions.

Land use change is typically applied by blending anthropogenic land surface disturbance via crop and pasture fraction changes with underlying land cover maps of natural vegetation, but model variations in the underlying land cover maps and biome modelling mean that the land use forcing agent is impossible to impose in a completely common way at present (Pitman et al., 2009). Most CMIP5 models represent crop and pasture disturbance separately, while some (Canadian Earth System Model (CanESM2), MIROC4h, MIROC5) represent crop but not pasture. Some models (e.g., HadGEM2-ES, MIROC-ESM and MPI-ESM versions) allow a dynamical representation of natural vegetation changes alongside anthropogenic disturbance (see also Sections 9.4.4.3 and 9.4.4.4).

Treatment of the CO_2 emissions associated with land cover changes is also model dependent. Some models do not account for land cover changes at all, some simulate the biophysical effects but are still forced externally by land cover change induced CO_2 emissions (in emissions-driven simulations), while the most advanced ESMs simulate both biophysical effects of land cover changes and their associated CO_2 emissions.

12.3.3 Synthesis of Projected Global Mean Radiative Forcing for the 21st Century

Quantification of future global mean RF is of interest as it is directly related to changes in the global energy balance of the climate system and resultant climate change. Chapter 8 discusses RF concepts and methods for computing it that form the basis of analysis directly from the output of model projections.

We assess three related estimates of projected global mean forcing and its range through the 21st century in the context of forcing estimated for the recent past (Figure 12.4). The estimates used are: the total forcings for the defined RCP scenarios, harmonized to RF in the past (Meinshausen et al., 2011a; Meinshausen et al., 2011c); the total effective radiative forcing (ERF) estimated from CMIP5 models through the 21st century for the four RCP experiments (Forster et al., 2013); and that estimated from models in the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP; Lamarque et al., 2013—see Section 8.2.2) for RCP time-slice experiments (Shindell et al., 2013b). Methodological differences mean that whereas CMIP5 estimates include both natural and anthropogenic forcings based entirely on ERF, ACCMIP estimates anthropogenic composition forcing only (neglecting forcing changes due to natural, i.e., solar and volcanic, and land use factors) based on a combination of ERF for aerosols and RF for WMGHG (see Section 8.5.3). Note also that total forcing for the defined RCP scenarios is based on Meinshausen et al. (2011c)

but combining total anthropogenic ERF (allowing for efficacies of the various anthropogenic forcings as in Figure 12.3) with natural (solar and volcanic) RF.

The CMIP5 multi-model ensemble mean ERF at 2100 (relative to an 1850–1869 base period) is 2.2, 3.8, 4.8 and 7.6 W m^{-2} respectively for RCP2.6, RCP4.5, RCP6.0 and RCP8.5 concentration-driven projections, with a 1-σ range based on annual mean data for year 2100 of about ±0.5 to 1.0 W m^{-2} depending on scenario (lowest for RCP2.6 and highest for RCP8.5). The CMIP5-based ERF estimates are close to the total forcing at 2100 (relative to an 1850–1859 base period) of 2.4, 4.0, 5.2 and 8.0 W m^{-2} as defined for the four RCPs.

The spread in ERF indicated from CMIP5 model results with specified GHG concentration pathways is broadly consistent with that found for CMIP3 models for the A1B scenario using the corresponding method (Forster and Taylor, 2006). As for CMIP3 models, part of the forcing spread in CMIP5 models (Forster et al., 2013) is consistent with differences in GHG forcings arising from the radiative transfer codes (Collins et al., 2006b). Aerosol forcing implementations in CMIP5 models also vary considerably, however (Section 12.3.2), leading to a spread in aerosol concentrations and forcings which contributes to the overall model spread. A further small source of spread in CMIP5 results possibly arises from an underlying ambiguity in the CMIP5 experimental design regarding the volcanic forcing offset between the historical experiment versus the pre-industrial control experiment. Most models implement zero volcanic forcing in the control experiment but some use constant negative forcing equal to the time-mean of historical volcanic forcing (see Table 12.1 and Section 12.3.2). The effect of this volcanic forcing offset persists into the future projections.

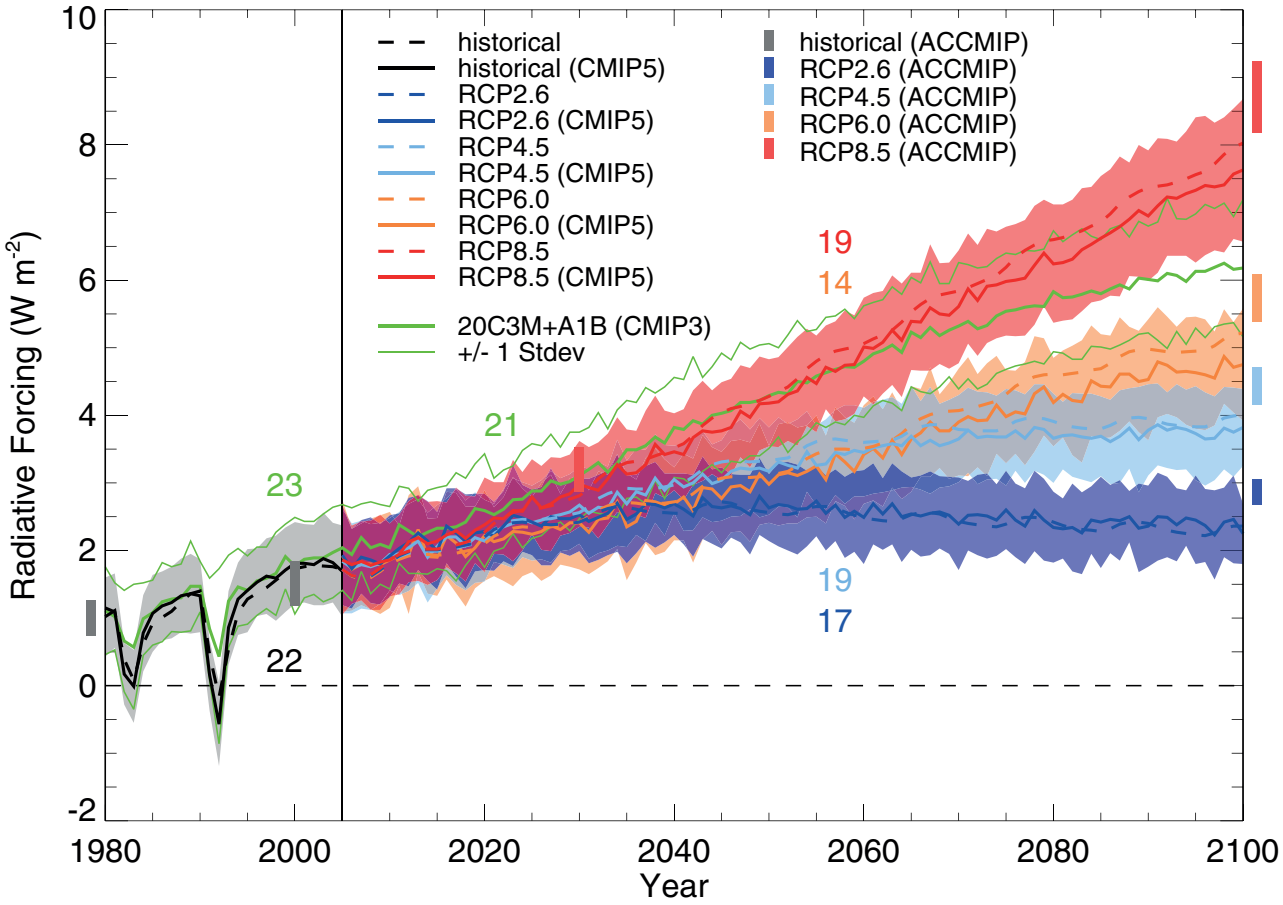

Figure 12.4 | Global mean radiative forcing (RF, W m^{-2}) between 1980 and 2100 estimated by alternative methods. The baseline is circa 1850 but dependent on the methods. Dashed lines indicate the total anthropogenic plus natural (solar and volcanic) RF for the RCP scenarios as defined by Meinshausen et al. (2011c), taking into account the efficacies of the various anthropogenic forcings (Meinshausen et al., 2011a), normalized by the mean between 1850 and 1859. Solid lines are multi-model mean effective radiative forcing (ERF) realized in a subset of CMIP5 models for the concentration-driven historical experiment and RCP scenarios, normalized either with respect to the 1850–1869 base period or with respect to the pre-industrial control simulation (Forster et al., 2013). (The subset of CMIP5 models included is defined by Table 1 of Forster et al. (2013) but omitting the FGOALS-s2 (Flexible Global Ocean-Atmosphere-Land System) model, the historical and RCP simulations of which were subsequently withdrawn from the CMIP5 archive.) This CMIP5-based estimate assumes each model has an invariant climate feedback parameter, calculated from abrupt 4 × CO_2 experiments using the method of Gregory et al. (2004). Each individual CMIP5 model's forcing estimate is an average over all available ensemble members, and a 1-σ inter-model range around the multi-model mean is shaded in light colour. Grey or coloured vertical bars illustrate the 1-σ range (68% confidence interval) of anthropogenic composition forcing (excluding natural and land use change forcings, based on ERF for aerosols combined with RF for WMGHG) estimated in ACCMIP models (Shindell et al., 2013b) for time slice experiments at 1980, 2000, 2030 (RCP8.5 only) and 2100 (all RCPs). The ACCMIP ranges plotted have been converted from the 5 to 95% ranges given in Shindell et al. (2013b) (Table 8) to a 1-σ range. Note that the ACCMIP bars at 1980 and 2100 are shifted slightly to aid clarity. The mean ERF diagnosed from 21 CMIP3 models for the SRES A1B scenario, as in Forster and Taylor (2006), is also shown (thick green line) with a 1-σ range (thinner green lines). The number of models included in CMIP3 and CMIP5 ensemble means is shown colour coded. (See Tables AII.6.8 to AII.6.10. Note that the CMIP5 model ranges given in Table AII.6.10 are based on decadal averages and therefore differ slightly from the ranges based on annual data shown in this figure.)

ACCMIP projected forcing at 2030 (for RCP8.5) and 2100 (all RCPs) is systematically higher than corresponding CMIP5 ERF, although with some overlap between 1-σ ranges. CMIP5 and ACCMIP comprise different sets of models and they are related in many but not all cases (Section 8.2.2). Confining analysis to a subset of closely related models also gives higher forcing estimates from ACCMIP compared to CMIP5 so the discrepancy in multi-model ensemble mean forcings appears unrelated to the different model samples associated with the two methods of estimation. The discrepancy is thought to originate mostly from differences in the underlying methodologies used to estimate RF, but is not yet well understood (see also Section 8.5.3).

There is *high confidence* in projections from ACCMIP models (Shindell et al., 2013b) based on the GISS-E2 CMIP5 simulations (Shindell et al., 2013a) and an earlier study with a version of the HadGEM2-ES model related to that used in CMIP5 (Bellouin et al., 2011), consistent with understanding of the processes controlling nitrate formation (Adams et al., 2001), that nitrate aerosols (which provide a negative forcing) will increase substantially over the 21st century under the RCPs (Section 8.5.3, Figure 8.20). The magnitude of total aerosol-related forcing (also negative in sign) will therefore tend to be underestimated in the CMIP5 multi-model mean ERF, as nitrate aerosol has been omitted as a forcing from almost all CMIP5 models.

Natural RF variations are, by their nature, difficult to project reliably (see Section 8.4). There is *very high confidence* that Industrial Era natural forcing has been a small fraction of the (positive) anthropogenic forcing except for brief periods following large volcanic eruptions (Sections 8.5.1 and 8.5.2). Based on that assessment and the assumption that variability in natural forcing remains of a similar magnitude and character to that over the Industrial Era, total anthropogenic forcing relative to pre-industrial, for any of the RCP scenarios through the 21st century, is *very likely* to be greater in magnitude than changes in natural (solar plus volcanic) forcing on decadal time scales.

In summary, global mean forcing projections derived from climate models exhibit a substantial range for the given RCP scenarios in concentration-driven experiments, contributing to the projected global mean temperature range (Section 12.4.1). Forcings derived from ACCMIP models for 2100 are systematically higher than those estimated from CMIP5 models for reasons that are not fully understood but are partly due to methodological differences. The multi-model mean estimate of combined anthropogenic plus natural forcing from CMIP5 is consistent with indicative RCP forcing values at 2100 to within 0.2 to 0.4 W m^{-2}.

12.4 Projected Climate Change over the 21st Century

12.4.1 Time-Evolving Global Quantities

12.4.1.1 Projected Changes in Global Mean Temperature and Precipitation

A consistent and robust feature across climate models is a continuation of global warming in the 21st century for all the RCP scenarios (Figure 12.5 showing changes in concentration-driven model simulations). Temperature increases are almost the same for all the RCP scenarios during the first two decades after 2005 (see Figure 11.25). At longer time scales, the warming rate begins to depend more on the specified GHG concentration pathway, being highest (>0.3°C per decade) in the highest RCP8.5 and significantly lower in RCP2.6, particularly after about 2050 when global surface temperature response stabilizes (and declines thereafter). The dependence of global temperature rise on GHG forcing at longer time scales has been confirmed by several studies (Meehl et al., 2007b). In the CMIP5 ensemble mean, global warming under RCP2.6 stays below 2°C above 1850-1900 levels throughout the 21st century, clearly demonstrating the potential of mitigation policies (note that to translate the anomalies in Figure 12.5 into anomalies with respect to that period, an assumed 0.61°C of observed warming since 1850–1900, as discussed in Section 2.4.3, should be added). This is in agreement with previous studies of aggressive mitigation scenarios (Johns et al., 2011; Meehl et al., 2012). Note, however, that some individual ensemble members do show warming exceeding 2°C above 1850-1900 (see Table 12.3). As for the other pathways, global warming exceeds 2°C within the 21st century under RCP4.5, RCP6.0 and RCP8.5, in qualitative agreement with previous studies using the SRES A1B and A2 scenarios (Joshi et al., 2011). Global mean temperature increase exceeds 4°C under RCP8.5 by 2100. The CMIP5 concentration-driven global temperature projections are broadly similar to CMIP3 SRES scenarios discussed in AR4 (Meehl et al., 2007b) and Section 12.4.9, although the overall range of the former is larger primarily because of the low-emission mitigation pathway RCP2.6 (Knutti and Sedláček, 2013).

The multi-model global mean temperature changes under different RCPs are summarized in Table 12.2. The relationship between cumulative anthropogenic carbon emissions and global temperature is assessed in Section 12.5 and only concentration-driven models are

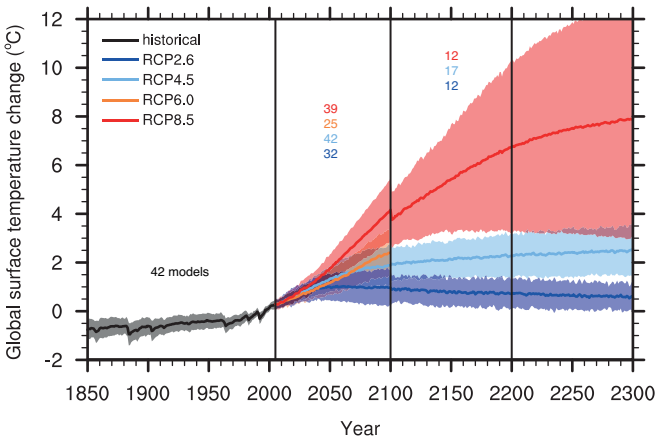

Figure 12.5 | Time series of global annual mean surface air temperature anomalies (relative to 1986–2005) from CMIP5 concentration-driven experiments. Projections are shown for each RCP for the multi-model mean (solid lines) and the 5 to 95% range (±1.64 standard deviation) across the distribution of individual models (shading). Discontinuities at 2100 are due to different numbers of models performing the extension runs beyond the 21st century and have no physical meaning. Only one ensemble member is used from each model and numbers in the figure indicate the number of different models contributing to the different time periods. No ranges are given for the RCP6.0 projections beyond 2100 as only two models are available.

Table 12.2 | CMIP5 annual mean surface air temperature anomalies (°C) from the 1986–2005 reference period for selected time periods, regions and RCPs. The multi-model mean ±1 standard deviation ranges across the individual models are listed and the 5 to 95% ranges from the models' distribution (based on a Gaussian assumption and obtained by multiplying the CMIP5 ensemble standard deviation by 1.64) are given in brackets. Only one ensemble member is used from each model and the number of models differs for each RCP (see Figure 12.5) and becomes significantly smaller after 2100. No ranges are given for the RCP6.0 projections beyond 2100 as only two models are available. Using Hadley Centre/Climate Research Unit gridded surface temperature data set 4 (HadCRUT4) and its uncertainty estimate (5 to 95% confidence interval), the observed warming to the 1986–2005 reference period (see Section 2.4.3) is 0.61°C ± 0.06°C (1850–1900), 0.30°C ± 0.03°C (1961–1990), 0.11°C ± 0.02°C (1980–1999). Decadal values are provided in Table AII.7.5, but note that percentiles of the CMIP5 distributions cannot directly be interpreted in terms of calibrated language.

		RCP2.6 (ΔT in °C)	RCP4.5 (ΔT in °C)	RCP6.0 (ΔT in °C)	RCP8.5 (ΔT in °C)
Global:	2046–2065	1.0 ± 0.3 (0.4, 1.6)	1.4 ± 0.3 (0.9, 2.0)	1.3 ± 0.3 (0.8, 1.8)	2.0 ± 0.4 (1.4, 2.6)
	2081–2100	1.0 ± 0.4 (0.3, 1.7)	1.8 ± 0.5 (1.1, 2.6)	2.2 ± 0.5 (1.4, 3.1)	3.7 ± 0.7 (2.6, 4.8)
	2181–2200	0.7 ± 0.4 (0.1, 1.3)	2.3 ± 0.5 (1.4, 3.1)	3.7 ± 0.7 (-,-)	6.5 ± 2.0 (3.3, 9.8)
	2281–2300	0.6 ± 0.3 (0.0, 1.2)	2.5 ± 0.6 (1.5, 3.5)	4.2 ± 1.0 (-,-)	7.8 ± 2.9 (3.0, 12.6)
Land: 2081–2100		1.2 ± 0.6 (0.3, 2.2)	2.4 ± 0.6 (1.3, 3.4)	3.0 ± 0.7 (1.8, 4.1)	4.8 ± 0.9 (3.4, 6.2)
Ocean: 2081–2100		0.8 ± 0.4 (0.2, 1.4)	1.5 ± 0.4 (0.9, 2.2)	1.9 ± 0.4 (1.1, 2.6)	3.1 ± 0.6 (2.1, 4.0)
Tropics: 2081–2100		0.9 ± 0.3 (0.3, 1.4)	1.6 ± 0.4 (0.9, 2.3)	2.0 ± 0.4 (1.3, 2.7)	3.3 ± 0.6 (2.2, 4.4)
Polar: Arctic: 2081–2100		2.2 ± 1.7 (-0.5, 5.0)	4.2 ± 1.6 (1.6, 6.9)	5.2 ± 1.9 (2.1, 8.3)	8.3 ± 1.9 (5.2, 11.4)
Polar: Antarctic: 2081–2100		0.8 ± 0.6 (-0.2, 1.8)	1.5 ± 0.7 (0.3, 2.7)	1.7 ± 0.9 (0.2, 3.2)	3.1 ± 1.2 (1.1, 5.1)

included here. Warming in 2046–2065 is slightly larger under RCP4.5 compared to RCP6.0, consistent with its greater total anthropogenic forcing at that time (see Table A.II.6.12). For all other periods the magnitude of global temperature change increases from RCP2.6 to RCP8.5. Beyond 2100, RCP2.6 shows a decreasing trend whereas under all other RCPs warming continues to increase. Also shown in Table 12.2 are projected changes at 2081–2100 averaged over land and ocean separately as well as area-weighted averages over the Tropics (30°S to 30°N), Arctic (67.5°N to 90°N) and Antarctic (90°S to 55°S) regions. Surface air temperatures over land warm more than over the ocean, and northern polar regions warm more than the tropics. The excess of land mass in the Northern Hemisphere (NH) in comparison with the Southern Hemisphere (SH), coupled with the greater uptake of heat by the Southern Ocean in comparison with northern ocean basins means that the NH generally warms more than the SH. Arctic warming is much greater than in the Antarctic, due to the presence of the Antarctic ice sheet and differences in local responses in snow and ice. Mechanisms behind these features of warming are discussed in Section 12.4.3. Maps and time series of regional temperature changes are displayed in Annex I and regional averages are discussed in Section 14.8.1.

Global annual multi-model mean temperature changes above 1850-1900 are listed in Table 12.3 for the 2081–2100 period (assuming 0.61°C warming since 1850–1900 as discussed in Section 2.4.3) along with the percentage of 2081–2100 projections from the CMIP5 models exceeding policy-relevant temperature levels under each RCP. These complement a similar discussion for the near-term projections in Table 11.3 which are based on the CMIP5 ensemble as well as evidence (discussed in Sections 10.3.1, 11.3.2.1.1 and 11.3.6.3) that some CMIP5 models have a higher sensitivity to GHGs and a larger response to other anthropogenic forcings (dominated by the effects of aerosols) than the real world (*medium confidence*). The percentage calculations for the long-term projections in Table 12.3 are based solely on the CMIP5 ensemble, using one ensemble member for each model. For these long-term projections, the 5 to 95% ranges of the CMIP5 model ensemble are considered the *likely* range, an assessment based on the fact that the 5 to 95% range of CMIP5 models' TCR coincides with the assessed *likely* range of the TCR (see Section 12.4.1.2 below and Box 12.2). Based on this assessment, global mean temperatures averaged in the period 2081–2100 are projected to *likely* exceed 1.5°C above 1850-1900 for RCP4.5, RCP6.0 and RCP8.5 (*high confidence*). They are also *likely* to exceed 2°C above 1850-1900 for RCP6.0 and RCP8.5 (*high confidence*) and *more likely than not* to exceed 2°C for RCP4.5 (*medium confidence*). Temperature change above 2°C under RCP2.6 is *unlikely* but is assessed only with *medium confidence* as some CMIP5 ensemble members do produce a global mean temperature change above 2°C. Warming above 4°C by 2081–2100 is *unlikely* in all RCPs (*high confidence*) except RCP8.5. Under the latter, the 4°C global temperature level is exceeded in more than half of ensemble members, and is assessed to be *about as likely as not* (*medium confidence*). Note that the likelihoods of exceeding specific temperature levels show some sensitivity to the choice of reference period (see Section 11.3.6.3).

CMIP5 models on average project a gradual increase in global precipitation over the 21st century: change exceeds 0.05 mm day^{-1} (~2% of global precipitation) and 0.15 mm day^{-1} (~5% of global precipitation) by 2100 in RCP2.6 and RCP8.5, respectively. The relationship between global precipitation and global temperature is approximately linear (Figure 12.6). The precipitation sensitivity, that is, the change of global precipitation with temperature, is about 1 to 3% °C^{-1} in most models, tending to be highest for RCP2.6 and RCP4.5 (Figure 12.7; note that only global values are discussed in this section, ocean and land changes are discussed in Section 12.4.5.2). These behaviours are consistent with previous studies, including CMIP3 model projections for SRES scenarios and AR4 constant composition commitment experiments (Meehl et al., 2007b), and ENSEMBLES multi-model results for SRES A1B and E1 scenarios (Johns et al., 2011).

The processes that govern global precipitation changes are now well understood and have been presented in Section 7.6. They are briefly summarized here and used to interpret the long-term projected changes. The precipitation sensitivity (about 1 to 3% °C^{-1}) is very different from the water vapour sensitivity (~7% °C^{-1}) as the main physical

Table 12.3 | CMIP5 global annual mean temperature changes above 1850-1900 for the 2081–2100 period of each RCP scenario (mean, ±1 standard deviation and 5 to 95% ranges based on a Gaussian assumption and obtained by multiplying the CMIP5 ensemble standard deviation by 1.64), assuming 0.61°C warming has occurred prior to 1986–2005 (second column). For a number of temperature levels (1°C, 1.5°C, 2°C, 3°C and 4°C), the proportion of CMIP5 model projections for 2081–2100 above those levels under each RCP scenario are listed. Only one ensemble member is used for each model.

	ΔT (°C) 2081–2100	ΔT > +1.0°C	ΔT > +1.5°C	ΔT > +2.0°C	ΔT > +3.0°C	ΔT > +4.0°C
RCP2.6	1.6 ± 0.4 (0.9, 2.3)	94%	56%	22%	0%	0%
RCP4.5	2.4 ± 0.5 (1.7, 3.2)	100%	100%	79%	12%	0%
RCP6.0	2.8 ± 0.5 (2.0, 3.7)	100%	100%	100%	36%	0%
RCP8.5	4.3 ± 0.7 (3.2, 5.4)	100%	100%	100%	100%	62%

laws that drive these changes also differ. Water vapour increases are primarily a consequence of the Clausius–Clapeyron relationship associated with increasing temperatures in the lower troposphere (where most atmospheric water vapour resides). In contrast, future precipitation changes are primarily the result of changes in the energy balance of the atmosphere and the way that these later interact with circulation, moisture and temperature (Mitchell et al., 1987; Boer, 1993; Vecchi and Soden, 2007; Previdi, 2010; O'Gorman et al., 2012). Indeed, the radiative cooling of the atmosphere is balanced by latent heating (associated with precipitation) and sensible heating. Since AR4, the changes in heat balance and their effects on precipitation have been analyzed in detail for a large variety of forcings, simulations and models (Takahashi, 2009a; Andrews et al., 2010; Bala et al., 2010; Ming et al., 2010; O'Gorman et al., 2012; Bony et al., 2013).

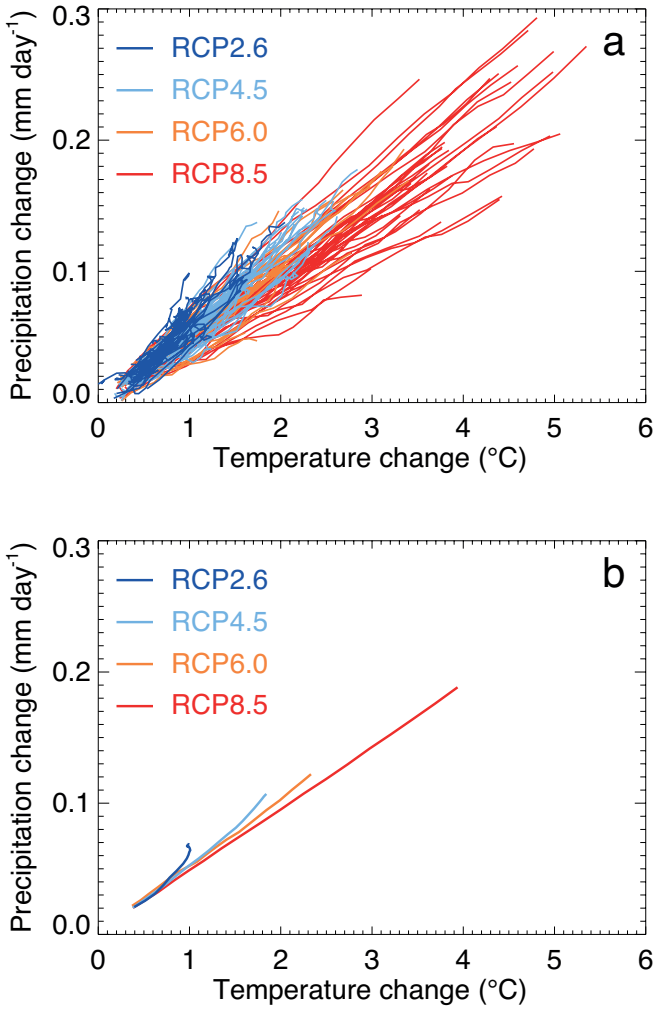

Figure 12.6 | Global mean precipitation (mm day^{-1}) versus temperature (°C) changes relative to 1986–2005 baseline period in CMIP5 model concentrations-driven projections for the four RCPs for (a) means over decadal periods starting in 2006 and overlapped by 5 years (2006–2015, 2011–2020, up to 2091–2100), each line representing a different model (one ensemble member per model) and (b) corresponding multi-model means for each RCP.

An increase of CO_2 decreases the radiative cooling of the troposphere and reduces precipitation (Andrews et al., 2010; Bala et al., 2010). On longer time scales than the fast hydrological adjustment time scale (Andrews et al., 2010; Bala et al., 2010; Cao et al., 2012; Bony et al., 2013), the increase of CO_2 induces a slow increase of temperature and water vapour, thereby enhancing the radiative cooling of the atmosphere and increasing global precipitation (Allen and Ingram, 2002; Yang et al., 2003; Held and Soden, 2006). Even after the CO_2 forcing stabilizes or begins to decrease, the ocean continues to warm, which then drives up global temperature, evaporation and precipitation. In addition, nonlinear effects also affect precipitation changes (Good et al., 2012). These different effects explain the steepening of the precipitation versus temperature relationship in RCP2.6 and RCP4.5 scenarios (Figure 12.6), as RF stabilizes and/or declines from the mid-century (Figure 12.4). In idealized CO_2 ramp-up/ramp-down experiments, this effect produces an hydrological response overshoot (Wu et al., 2010). An increase of absorbing aerosols warms the atmosphere and reduces precipitation, and the surface temperature response may be too small to compensate this decrease (Andrews et al., 2010; Ming et al., 2010; Shiogama et al., 2010a). Change in scattering aerosols or incoming solar radiation modifies global precipitation mainly via the response of the surface temperature (Andrews et al., 2009; Bala et al., 2010).

The main reasons for the inter-model spread of the precipitation sensitivity estimate among GCMs have not been fully understood. Nevertheless, spread in the changes of the cloud radiative effect has been shown to have an impact (Previdi, 2010), although the effect is less important for precipitation than it is for the climate sensitivity estimate (Lambert and Webb, 2008). The lapse rate plus water vapour feedback and the response of the surface heat flux (Previdi, 2010; O'Gorman et al., 2012), the shortwave absorption by water vapour (Takahashi, 2009b) or by aerosols, have been also identified as important factors.

Global precipitation sensitivity estimates from observations are very sensitive to the data and the time period considered. Some

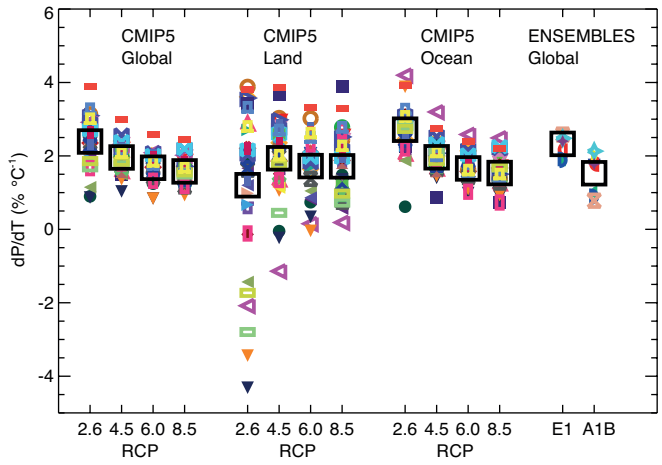

Figure 12.7 | Percentage changes over the 21st century in global, land and ocean precipitation per degree Celsius of global warming in CMIP5 model concentration-driven projections for the four RCP scenarios. Annual mean changes are calculated for each year between 2006 and 2100 from one ensemble member per model relative to its mean precipitation and temperature for the 1986–2005 baseline period, and the gradient of a least-squares fit through the annual data is derived. Land and ocean derived values use global mean temperature in the denominator of $\delta P/\delta T$. Each coloured symbol represents a different model, the same symbol being used for the same model for different RCPs and larger black squares being the multi-model mean. Also shown for comparison are global mean results for ENSEMBLES model concentrations-driven projections for the E1 and A1B scenarios (Johns et al., 2011), in this case using a least-squares fit derived over the period 2000–2099 and taking percentage changes relative to the 1980–1999 baseline period. Changes of precipitation over land and ocean are discussed in Section 12.4.5.2.

observational studies suggest precipitation sensitivity values higher than model estimates (Wentz et al., 2007; Zhang et al., 2007), although more recent studies suggest consistent values (Adler et al., 2008; Li et al., 2011b).

12.4.1.2 Uncertainties in Global Quantities

Uncertainties in global mean quantities arise from variations in internal natural variability, model response and forcing pathways. Table 12.2 gives two measures of uncertainty in the CMIP5 model projections, the standard deviation and the 5 to 95% range across the ensemble's distribution. Because CMIP5 was not designed to explore fully the uncertainty range in projections (see Section 12.2), neither its standard deviation nor its range can be interpreted directly as an uncertainty statement about the corresponding real quantities, and other techniques and arguments to assess uncertainty in future projections must be considered. Figure 12.8 summarizes the uncertainty ranges in global mean temperature changes at the end of the 21st century under the various scenarios quantified by various methods. Individual CMIP5 models are shown by red crosses. Red bars indicate mean and 5 to 95% percentiles based on assuming a normal distribution for the CMIP5 sample (i.e., ±1.64 standard deviations). Estimates from the simple climate carbon cycle Model for the Assessment of Greenhouse Gas-Induced Climate Change (MAGICC; Meinshausen et al., 2011a; Meinshausen et al., 2011b) calibrated to C^{4}MIP (Friedlingstein et al., 2006) carbon cycle models, assuming a PDF for climate sensitivity that corresponds to the assessment of IPCC AR4 (Meehl et al., 2007b, Box 10.2), are given as yellow bars (Rogelj et al., 2012). Note that not all models have simulated all scenarios. To test the effect of undersampling, and to generate a consistent set of uncertainties across scenarios, a step response method that estimates the total warming as sum of responses to small forcing steps (Good et al., 2011a) is used to emulate 23 CMIP5 models under the different scenarios (those 23 models that supplied the necessary simulations to compute the emulators, i.e., CO_2 step change experiments). This provides means and ranges (5 to 95%) that are comparable across scenarios (blue). See also Section 12.4.9 for a discussion focussed on the differences between CMIP3 and CMIP5 projections of global average temperature changes.

For the CO_2 concentration-driven simulations (Figure 12.8a), the dominant driver of uncertainty in projections of global temperature for the higher RCPs beyond 2050 is the transient climate response (TCR), for RCP2.6, which is closer to equilibrium by the end of the century, it is both the TCR and the equilibrium climate sensitivity (ECS). In a transient situation, the ratio of temperature to forcing is approximately constant and scenario independent (Meehl et al., 2007b, Appendix 10.A.1; Gregory and Forster, 2008; Knutti et al., 2008b; Good et al., 2013). Therefore, the uncertainty in TCR maps directly into the uncertainty in global temperature projections for the RCPs other than RCP2.6. The assessed *likely* range of TCR based on various lines of evidence (see Box 12.2) is similar to the 5 to 95% percentile range of TCR in CMIP5. In addition, the assessed *likely* range of ECS is also consistent with the CMIP5 range (see Box 12.2). There is little evidence that the CMIP5 models are significantly over- or underestimating the RF. The RF uncertainty is small compared to response uncertainty (see Figure 12.4), and is considered by treating the 5 to 95% as a *likely* rather than *very likely* range. Kuhlbrodt and Gregory (2012) suggest that models might be overestimating ocean heat uptake, as previously suggested by Forest et al. (2006), but observationally constrained estimates of TCR are unaffected by that. The ocean heat uptake efficiency does not contribute much to the spread of TCR (Knutti and Tomassini, 2008; Kuhlbrodt and Gregory, 2012).

Therefore, for global mean temperature projections only, the 5 to 95% range (estimated as 1.64 times the sample standard deviation) of the CMIP5 projections can also be interpreted as a *likely* range for future temperature change between about 2050 and 2100. *Confidence* in this assessment is *high* for the end of the century because the warming then is dominated by CO_2 and the TCR. *Confidence* is only *medium* for mid-century when the contributions of RF and initial conditions to the total temperature response uncertainty are larger. The *likely* ranges are an expert assessment, taking into account many lines of evidence, in much the same way as in AR4 (Figure SPM.5), and are not probabilistic. The *likely* ranges for 2046–2065 do not take into account the possible influence of factors that lead to near-term (2016–2035) projections of global mean surface temperature (GMST) that are somewhat cooler than the 5 to 95% model ranges (see Section 11.3.6), because the influence of these factors on longer term projections cannot be quantified. A few recent studies indicate that some of the models with the strongest transient climate response might overestimate the near term warming (Otto et al., 2013; Stott et al., 2013) (see Sections 10.8.1, 11.3.2.1.1), but there is little evidence of whether and how much that affects the long-term warming response. One perturbed physics ensemble combined with observations indicates warming that exceeds the AR4 at the top end but used a relatively short time period of warming

(50 years) to constrain the models' projections (Rowlands et al., 2012) (see Sections 11.3.2.1.1 and 11.3.6.3). GMSTs for 2081–2100 (relative to 1986–2005) for the CO_2 concentration driven RCPs is therefore assessed to *likely* fall in the range 0.3°C to 1.7°C (RCP2.6), 1.1°C to 2.6°C (RCP4.5), 1.4°C to 3.1°C (RCP6.0), and 2.6°C to 4.8°C (RCP8.5) estimated from CMIP5. Beyond 2100, the number of CMIP5 simulations is insufficient to estimate a *likely* range. Uncertainties before 2050 are assessed in Section 11.3.2.1.1. The assessed *likely* range is very similar to the range estimated by the pulse response model, suggesting that the different sample of models for the different RCPs are not strongly affecting the result, and providing further support that this pulse response technique can be used to emulate temperature and ocean heat uptake in Chapter 13 and Section 12.4.9. The results are consistent with the probabilistic results from MAGICC, which for the lower RCPs have a slightly narrower range due to the lack of internal variability in the simple model, and the fact that non-CO_2 forcings are treated more homogeneously than in CMIP5 (Meinshausen et al., 2011a, 2011b). This is particularly pronounced for RCP2.6 where the CMIP5 range is substantially larger, partly due to the larger fraction of non-CO_2 forcings in that scenario.

The uncertainty estimate in AR4 for the SRES scenarios was –40% to +60% around the CMIP3 means (shown here in grey for comparison). That range was asymmetric and wider for the higher scenarios because it included the uncertainty in carbon cycle climate feedbacks. The SRES scenarios are based on the assumption of prescribed emissions, which then translates to uncertainties in concentrations that propagate through to uncertainties in the temperature response. The RCP scenarios assume prescribed concentrations. For scenarios that stabilize (RCP2.6) that approach of constant fractional uncertainty underestimates the uncertainty and is no longer applicable, mainly because internal variability has a larger relative contribution to the total uncertainty (Good et al., 2013; Knutti and Sedláček, 2013). For the RCPs, the carbon cycle climate feedback uncertainty is not included because the simulations are driven by concentrations. Furthermore, there is no clear evidence that distribution of CMIP5 global temperature changes deviates from a normal distribution. For most other variables the shape of the distribution is unclear, and standard deviations are simply used as an indication of model spread, not representing a formal uncertainty assessment.

Simulations with prescribed CO_2 emissions rather than concentrations are only available for RCP8.5 (Figure 12.8b) and from MAGICC. The projected temperature change in 2100 is slightly higher and the uncertainty range is wider as a result of uncertainties in the carbon cycle climate feedbacks. The CMIP5 range is consistent with the uncertainty range given in AR4 for SRES A2 in 2100. Further details about emission versus concentration driven simulations are given in Section 12.4.8.

In summary, the projected changes in global temperature for 2100 in the RCP scenarios are very consistent with those obtained by CMIP3 for SRES in IPCC AR4 (see Section 12.4.9) when taking into account the differences in scenarios. The *likely* uncertainty ranges provided here are similar for RCP4.5 and RCP6.0 but narrower for RCP8.5 compared to AR4. There was no scenario as low as RCP2.6 in AR4. The uncertainties in global temperature projections have not decreased significantly in CMIP5 (Knutti and Sedláček, 2013), but the assessed ranges cannot be compared between AR4 and AR5. The main reason is that uncertainties in carbon cycle feedbacks are not considered in the concentration driven RCPs. In contrast, the *likely* range in AR4 included those. The assessed *likely* ranges are therefore narrower for the high RCPs. The differences in the projected warming are largely attributable to the difference in scenarios (Knutti and Sedláček, 2013), and the change in the future and reference period, rather than to developments in modelling since AR4. A detailed comparison between the SRES and RCP scenarios and the CMIP3 and CMIP5 models is given in Section 12.4.9.

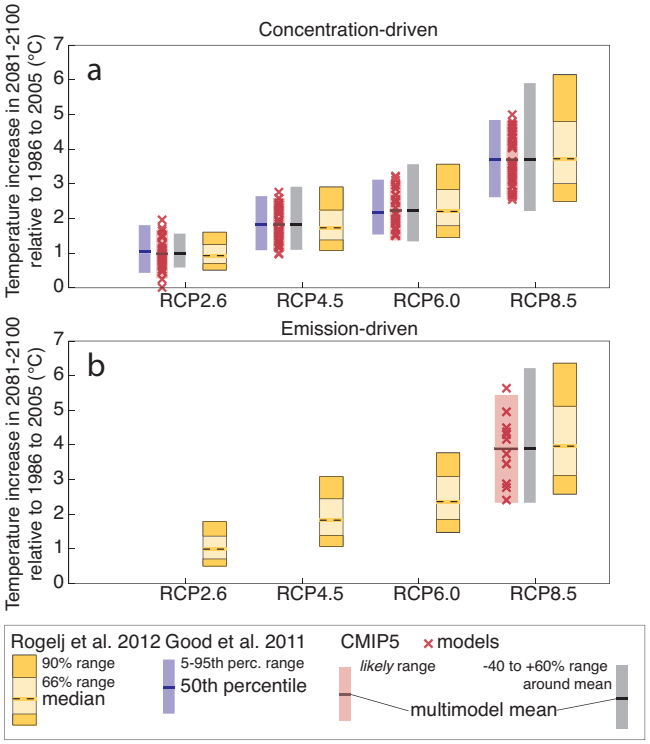

Figure 12.8 | Uncertainty estimates for global mean temperature change in 2081–2100 with respect to 1986–2005. Red crosses mark projections from individual CMIP5 models. Red bars indicate mean and 5 to 95% ranges based on CMIP5 (1.64 standard deviations), which are considered as a *likely* range. Blue bars indicate 5 to 95% ranges from the pulse response emulation of 21 models (Good et al., 2011a). Grey bars mark the range from the mean of CMIP5 minus 40% to the mean +60%, assessed as *likely* in AR4 for the SRES scenarios. The yellow bars show the median, 17 to 83% range and 5 to 95% range based on Rogelj et al. (2012). See also Figures 12.39 and 12.40.

12.4.2 Pattern Scaling

12.4.2.1 Definition and Use

In this chapter we show geographical patterns of projected changes in climate variables according to specific scenarios and time horizons. Alternative scenarios and projection times can be inferred from those shown by using some established approximation methods. This is especially the case for large-scale regional patterns of average temperature and—with additional caveats—precipitation changes. In fact, 'pattern scaling' is an approximation that has been explicitly suggested in the description of the RCPs (Moss et al., 2010) as a method for deriving impact-relevant regional projections for scenarios that have not been simulated by global and regional climate models. It was first proposed

by Santer et al. (1990) and revisited later by numerous studies (e.g., Huntingford and Cox, 2000). It relies on the existence of robust geographical patterns of change, emerging at the time when the response to external forcings emerges from the noise, and persisting across the length of the simulation, across different scenarios, and even across models, modulated by the corresponding changes in global average temperature. The robustness of temperature change patterns has been amply documented from the original paper onward. An example is given in Figure 12.9 for surface air temperature from each of the CMIP5 models highlighting both similarities and differences between the responses of different models. The precipitation pattern was shown to scale linearly with global average temperature to a sufficient accuracy in CMIP3 models (Neelin et al., 2006) for this to be useful for projections related to the hydrological cycle. Shiogama et al. (2010b) find similar results with the caution that in the early stages of warming aerosols modify the pattern. A more mixed evaluation can be found in

Figure 12.9 | Surface air temperature change in 2081–2100 displayed as anomalies with respect to 1986–2005 for RCP4.5 from one ensemble member of each of the concentration-driven models available in the CMIP5 archive.

Good et al. (2012), where some land areas in the low latitudes exhibit a nonlinear relation to global average temperature, but, largely, average precipitation change over the remaining regions can be well approximated by a grid-point specific linear function of global average temperature change. It is in the latter quantity that the dependence of the evolution of the change in time on the model (e.g., its climate sensitivity) and the forcing (e.g., the emission scenario) is encapsulated.

In analytical terms, it is assumed that the following relation holds:

$$C\,(t,\xi) = T_G(t)\,\chi(\xi) + R\,(t,\,\xi)$$

where the symbol ξ identifies the geographic location (model grid point or other spatial coordinates) and possibly the time of year (e.g., a June–July–August average). The index t runs along the length of the forcing scenario of interest. $T_G(t)$ indicates global average temperature change at time t under this scenario; $\chi(\xi)$ is the time-invariant geographic pattern of change per 1°C global surface temperature change for the variable of interest (which represents the forced component of the change) and $C\,(t,\xi)$ is the actual field of change for that variable at the specific time t under this scenario. The $R\,(t,\,\xi)$ is a residual term and highlights the fact that pattern scaling cannot reconstruct model behaviour with complete accuracy due to both natural variability and because of limitations of the methodology discussed below. This way, regionally and temporally differentiated results under different scenarios or climate sensitivities can be approximated by the product of a spatial pattern, constant over time, scenario and model characteristics, and a time evolving global mean change in temperature. Model and scenario dependence are thus captured through the global mean temperature response, and simple climate models calibrated against fully coupled climate models can be used to simulate the latter, at a great saving in computational cost. The spatial pattern can be estimated through the available coupled model simulations under the assumption that it does not depend on the specific scenario(s) used.

The choice of the pattern in the studies available in the literature can be as simple as the ensemble average field of change (across models and/or across scenarios, for the coupled experiments available), normalized by the corresponding change in global average temperature, choosing a segment of the simulations when the signal has emerged from the noise of natural variability from a baseline of reference (e.g., the last 20 years of the 21st century compared to pre-industrial or current climate) and taking the difference of two multi-decadal means. Similar properties and results have been obtained using more sophisticated multivariate procedures that optimize the variance explained by the pattern (Holden and Edwards, 2010). The validity of this approximation is discussed by Mitchell et al. (1999) and Mitchell (2003). Huntingford and Cox (2000) evaluate the quality of the approximation for numerous variables, showing that the technique performs best for temperature, downward longwave radiation, relative humidity, wind speeds and surface pressure while showing relatively larger limitations for rainfall rate anomalies. Joshi et al. (2013) have recently shown that the accuracy of the approximation, especially across models, is improved by adding a second term, linear in the land–sea surface warming ratio, another quantity that can be easily estimated from existing coupled climate model simulations. There exist of course differences between the patterns generated by different GCMs (documented for example for CMIP3 in Watterson and Whetton, 2011b), but uncertainty can be characterized, for example, by the inter-model spread in the pattern $\chi(\xi)$. Recent applications of the methodology to probabilistic future projections have in fact sought to fully quantify errors introduced by the approximation, on the basis of the available coupled model runs (Harris et al., 2006).

Pattern scaling and its applications have been documented in IPCC WGI Reports before (IPCC, 2001, Section 13.5.2.1; Meehl et al., 2007b, Section 10.3.2). It has been used extensively for regional temperature and precipitation change projections, for example, Murphy et al. (2007), (Watterson, 2008), Giorgi (2008), Harris et al. (2006, 2010), May (2008a), Ruosteenoja et al. (2007), Räisänen and Ruokolainen (2006), Cabre et al. (2010) and impact studies, for example, as described in Dessai et al. (2005) and Fowler et al. (2007b). Recent studies have focussed on patterns linked to warming at certain global average temperature change thresholds (e.g., May, 2008a; Sanderson et al., 2011) and patterns derived under the RCPs (Ishizaki et al., 2012).

There are basic limitations to this approach, besides a degradation of its performance as the regional scale of interest becomes finer and in the presence of regionally specific forcings. Recent work with MIROC3.2 (Shiogama et al., 2010a; Shiogama et al., 2010b) has revealed a dependence of the precipitation sensitivity (global average precipitation change per 1°C of global warming—see Figure 12.6) on the scenario, due to the precipitation being more sensitive to carbon aerosols than WMGHGs. In fact, there are significant differences in black and organic carbon aerosol forcing between the emission scenarios investigated by Shiogama et al. (2010a; 2010b). Levy II et al. (2013) confirm that patterns of precipitation change are spatially correlated with the sources of aerosol emissions, in simulations where the indirect effect is represented. This is a behaviour that is linked to a more general limitation of pattern scaling, which breaks down if aerosol forcing is significant. The effects of aerosols have a regional nature and are thus dependent on the future sources of pollution which are likely to vary geographically in the future and are difficult to predict (May, 2008a). For example, Asian and North American aerosol production are likely to have different time histories and future projections. Schlesinger et al. (2000) extended the methodology of pattern scaling by isolating and recombining patterns derived by dedicated experiments with a coupled climate model where sulphate aerosols were increased for various regions in turn. More recently, in an extension of pattern scaling into a probabilistic treatment of model, scenario and initial condition uncertainties, Frieler et al. (2012) derived joint probability distributions for regionally averaged temperature and precipitation changes as linear functions of global average temperature and additional predictors including regionally specific sulphate aerosol and black carbon emissions.

Pattern scaling is less accurate for strongly mitigated stabilization scenarios. This has been shown recently by May (2012), comparing patterns of temperature change under a scenario limiting global warming since pre-industrial times to 2°C and patterns produced by a scenario that reaches 4.5°C of global average temperature change. The limitations of pattern scaling in approximating changes while the climate system approaches equilibrium have found their explanation in Manabe and Wetherald (1980) and Mitchell et al. (1999). Both studies point out that as the temperatures of the deep oceans reach equilibri-

um (over multiple centuries) the geographical distribution of warming changes as well, for example, showing a larger warming of the high latitudes in the SH than in the earlier periods of the transient response, relative to the global mean warming. More recently, Held et al. (2010) showed how this slow warming pattern is in fact present during the initial transient response of the system as well, albeit with much smaller amplitude. Further, Gillett et al. (2011) show how in a simulation in which emissions cease, regional temperatures and precipitation patterns exhibit ongoing changes, even though global mean temperature remains almost constant. Wu et al. (2010) showed that the global precipitation response shows a nonlinear response to strong mitigation scenarios, with the hydrological cycle continuing to intensify even after atmospheric CO_2 concentration, and thus global average temperature, start decreasing. Regional nonlinear responses to mitigation scenarios of precipitation and sea surface temperatures (SSTs) are shown by Chadwick et al. (2013).

Other areas where pattern scaling shows a lack of robustness are the edges of polar ice caps and sea ice extent, where at an earlier time in the simulation ice melts and regions of sharp gradient surface, while later in the simulation, in the absence of ice, the gradient will become less steep. Different sea ice representations in models also make the location of such regions much less robust across the model ensembles and the scenarios.

Pattern scaling has not been as thoroughly explored for quantities other than average temperature and precipitation. Impact relevant extremes, for example, seem to indicate a critical dependence on the scale at which their changes are evaluated, with studies showing that some aspects of their statistics change in a close-to-linear way with mean temperature (Kharin et al., 2007; Lustenberger et al., 2013) while others have documented the dependence of their changes on moments of their statistical distribution other than the mean (Ballester et al., 2010a), which would make pattern scaling inadequate.

12.4.2.2 Coupled Model Intercomparison Project Phase 5 Patterns Scaled by Global Average Temperature Change

On the basis of CMIP5 simulations, we show geographical patterns (Figure 12.10) of warming and precipitation change and indicate measures of their variability across models and across RCPs. The patterns are scaled to 1°C global mean surface temperature change above the reference period 1986–2005 for 2081–2100 (first row) and for a period of approximate stable temperature, 2181–2200 (thus excluding RCP8.5, which does not stabilize by that time) (second row). Spatial correlation of fields of temperature and precipitation change range from 0.93 to 0.99 when considering ensemble means under different RCPs. The lower values are found when computing correlation between RCP2.6 and the higher RCPs, and may be related to the high mitigation

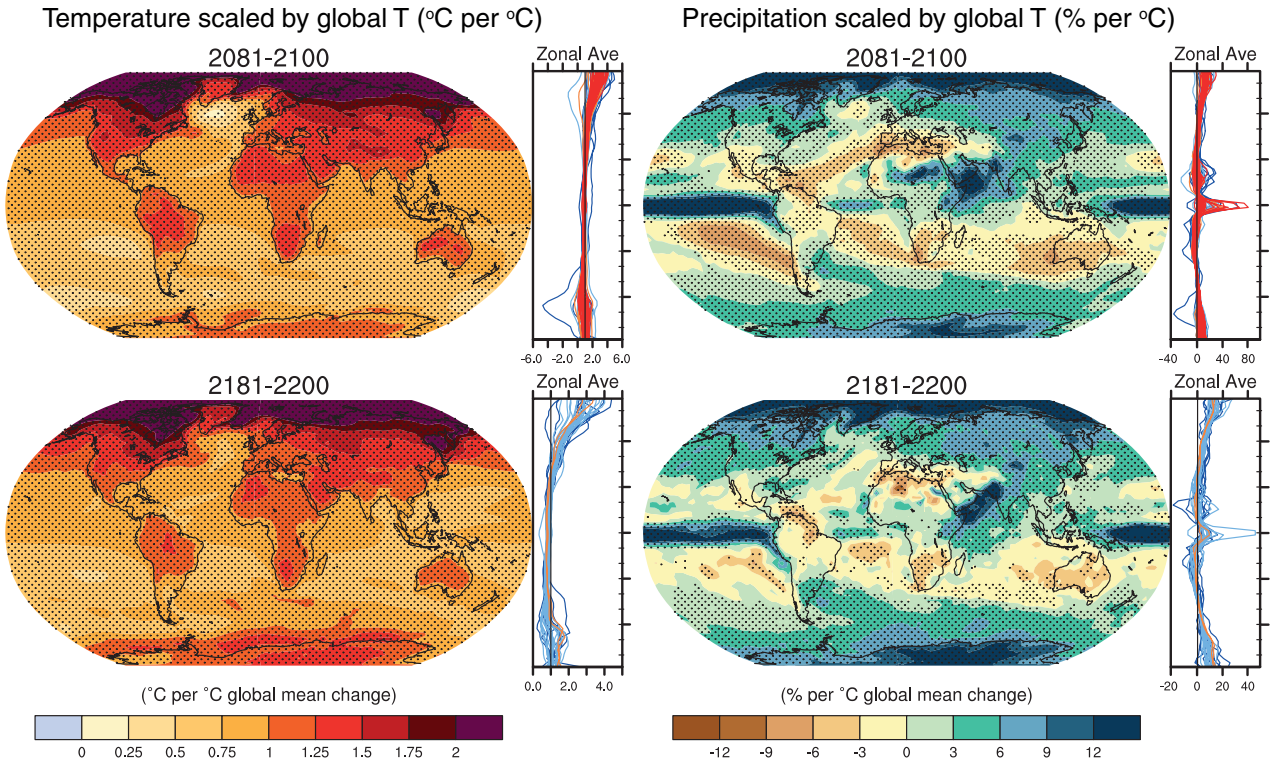

Figure 12.10 | Temperature (left) and precipitation (right) change patterns derived from transient simulations from the CMIP5 ensembles, scaled to 1°C of global mean surface temperature change. The patterns have been calculated by computing 20-year averages at the end of the 21st (top) and 22nd (bottom) centuries and over the period 1986–2005 for the available simulations under all RCPs, taking their difference (percentage difference in the case of precipitation) and normalizing it, grid-point by grid-point, by the corresponding value of global average temperature change for each model and scenario. The normalized patterns have then been averaged across models and scenarios. The colour scale represents degrees Celsius (in the case of temperature) and percent (in the case of precipitation) per 1°C of global average temperature change. Stippling indicates where the mean change averaged over all realizations is larger than the 95% percentile of the distribution of models. Zonal means of the geographical patterns are shown for each individual model for RCP2.6 (blue), 4.5 (light blue), 6.0 (orange) and 8.5 (red). RCP8.5 is excluded from the stabilization figures. The RCP2.6 simulation of the FIO-ESM (First Institute of Oceanography) model was excluded because it did not show any warming by the end of the 21st century, thus not complying with the method requirement that the pattern be estimated at a time when the temperature change signal from CO_2 increase has emerged.

enacted under RCP2.6 from early in the 21st century. Pattern correlation varies between 0.91 and 0.98 for temperature and between 0.91 and 0.96 for precipitation when comparing patterns computed by averaging and normalizing changes at the end of the 21st, 22nd and 23rd centuries, with the largest value representing the correlation between the patterns at the end of the 22nd and 23rd centuries, the lowest representing the correlation between the pattern at the end of the 21st and the pattern at the end of the 23rd century. The zonal means shown to the side of each plot represent each model by one line, colour coding the four different scenarios. They show good agreement of models and scenarios over low and mid-latitudes for temperature, but higher spread across models and especially across scenarios for the areas subject to polar amplification, for which the previous discussion about the sensitivity of the patterns to the sea ice edge may be relevant. A comparison of the mean of the lines to their spread indicates overall the presence of a strong mean signal with respect to the spread of the ensemble. Precipitation shows an opposite pattern of inter-model spread, with larger variations in the low latitudes and around the equator, and smaller around the high latitudes. Precipitation has also a lower signal-to-noise ratio (measured as above by comparing the ensemble mean change magnitude to the spread across models and scenarios of these zonal mean averages).

As already mentioned, although we do not explicitly use pattern scaling in the sections that follow, we consider it a useful approximation when the need emerges to interpolate or extrapolate results to different scenarios or time periods, noting the possibility that the scaling may break down at higher levels of global warming, and that the validity of the approximation is limited to broad patterns of change, as opposed to local scales. An important caveat is that pattern scaling only applies to the climate response that is externally forced. The actual response is a combination of forced change and natural variability, which is not and should not be scaled up or down by the application of this technique, which becomes important on small spatial scales and shorter time scales, and whose relative magnitude compared to the forced component also depends on the variable (Hawkins and Sutton, 2009, 2011; Mahlstein et al., 2011; Deser et al., 2012a, 2012b; Mahlstein et al., 2012) (see Section 11.2). One approach to produce projections that include both components is to estimate natural variability separately, scale the forced response and add the two.

12.4.3 Changes in Temperature and Energy Budget

12.4.3.1 Patterns of Surface Warming: Land–Sea Contrast, Polar Amplification and Sea Surface Temperatures

Patterns of surface air temperature change for various RCPs show widespread warming during the 21st century (Figure 12.11; see Annex I for seasonal patterns). A key feature that has been present throughout the history of coupled modelling is the larger warming over land compared to oceans, which occurs in both transient and equilibrium climate change (e.g., Manabe et al., 1990). The degree to which warming is larger over land than ocean is remarkably constant over time under transient warming due to WMGHGs (Lambert and Chiang, 2007; Boer, 2011; Lambert et al., 2011) suggesting that heat capacity differences between land and ocean do not play a major role in the land–sea warming contrast (Sutton et al., 2007; Joshi et al., 2008, 2013). The phenomenon is predominantly a feature of the surface and lower atmosphere (Joshi et al., 2008). Studies have found it occurs due to contrasts in surface sensible and latent fluxes over land (Sutton et al., 2007), land–ocean contrasts in boundary layer lapse rate changes (Joshi et al., 2008), boundary layer relative humidity and associated low-level cloud cover changes over land (Doutriaux-Boucher et al., 2009; Fasullo, 2010) and soil moisture reductions (Dong et al., 2009; Clark et al., 2010) under climate change. The land–sea warming contrast is also sensitive to aerosol forcing (Allen and Sherwood, 2010; Joshi et al., 2013). Globally averaged warming over land and ocean is identified separately in Table 12.2 for the CMIP5 models and the ratio of land to ocean warming is *likely* in the range of 1.4 to 1.7, consistent with previous studies (Lambert et al., 2011). The CMIP5 multi-model mean ratio is approximately constant from 2020 through to 2100 (based on an update of Joshi et al., 2008 from available CMIP5 models).

Amplified surface warming in Arctic latitudes is also a consistent feature in climate model integrations (e.g., Manabe and Stouffer, 1980). This is often referred to as polar amplification, although numerous studies have shown that under transient forcing, this is primarily an Arctic phenomenon (Manabe et al., 1991; Meehl et al., 2007b). The lack of an amplified transient warming response in high Southern polar latitudes has been associated with deep ocean mixing, strong ocean heat uptake and the persistence of the vast Antarctic ice sheet. In equilibrium simulations, amplified warming occurs in both polar regions.

On an annual average, and depending on the forcing scenario (see Table 12.2), the CMIP5 models show a mean Arctic (67.5°N to 90°N) warming between 2.2 and 2.4 times the global average warming for 2081–2100 compared to 1986–2005. Similar polar amplification factors occurred in earlier coupled model simulations (e.g., Holland and Bitz, 2003; Winton, 2006a). This factor in models is slightly higher than the observed central value, but it is within the uncertainty of the best estimate from observations of the recent past (Bekryaev et al., 2010). The uncertainty is large in the observed factor because station records are short and sparse (Serreze and Francis, 2006) and the forced signal is contaminated by the noise of internal variability. By contrast, model trends in surface air temperature are 2.5 to 5 times higher than observed over Antarctica, but here also the observational estimates have a very large uncertainty, so, for example, the CMIP3 ensemble mean is consistent with observations within error estimates (Monaghan et al., 2008). Moreover, recent work suggests more widespread current West Antarctic surface warming than previously estimated (Bromwich et al., 2013).

The amplified Arctic warming in models has a distinct seasonal character (Manabe and Stouffer, 1980; Rind, 1987; Holland and Bitz, 2003; Lu and Cai, 2009; Kumar et al., 2010). Arctic amplification (defined as the 67.5 N° to 90°N warming compared to the global average warming for 2081–2100 versus 1986–2005) peaks in early winter (November to December) with a CMIP5 RCP4.5 multi-model mean warming for 67.5°N to 90°N exceeding the global average by a factor of more than 4. The warming is smallest in summer when excess heat at the Arctic surface goes into melting ice or is absorbed by the ocean, which has a relatively large thermal inertia. Simulated Arctic warming also has a consistent vertical structure that is largest in the lower troposphere

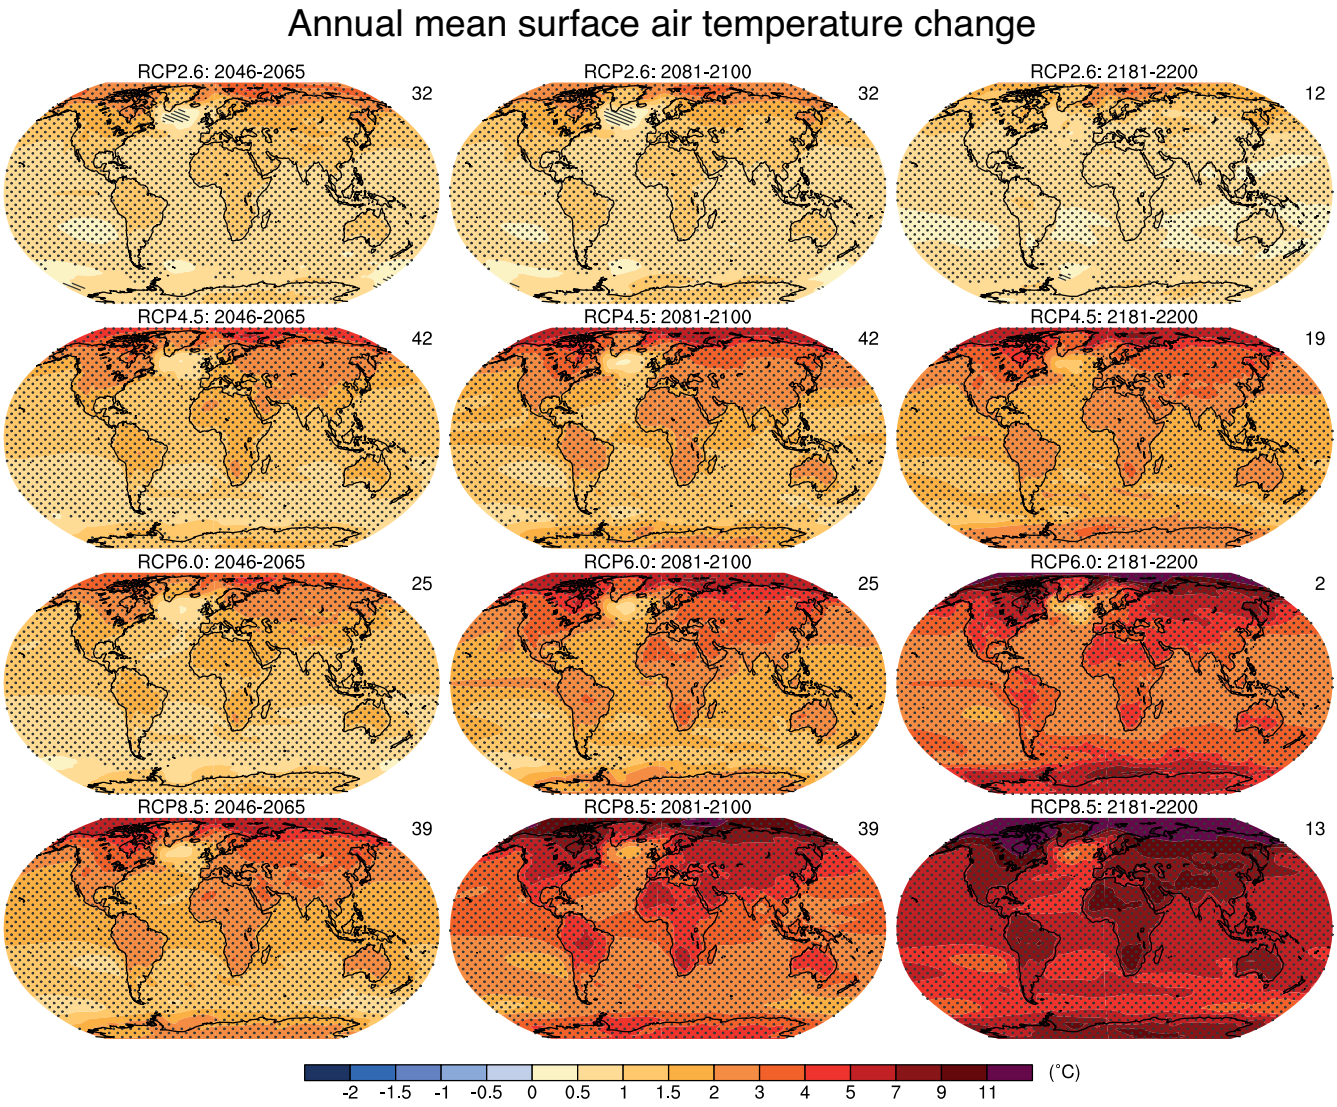

Figure 12.11 | Multi-model ensemble average of surface air temperature change (compared to 1986–2005 base period) for 2046–2065, 2081–2100, 2181–2200 for RCP2.6, 4.5, 6.0 and 8.5. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

(e.g., Manabe et al., 1991; Kay et al., 2012). This is in agreement with recent observations (Serreze et al., 2009; Screen and Simmonds, 2010) but contrary to an earlier study that suggested a larger warming aloft (Graversen et al., 2008). The discrepancy in observed vertical structure may reflect inadequacies in data sets (Bitz and Fu, 2008; Grant et al., 2008; Thorne, 2008) and sensitivity to the time period used for averaging (see also Box 2.3).

As also discussed in Box 5.1, there are many mechanisms that contribute to Arctic amplification, some of which were identified in early modelling studies (Manabe and Stouffer, 1980). Feedbacks associated with changes in sea ice and snow amplify surface warming near the poles (Hall, 2004; Soden et al., 2008; Graversen and Wang, 2009; Kumar et al., 2010). The longwave radiation changes in the top of the atmosphere associated with surface warming opposes surface warming at all latitudes, but less so in the Arctic (Winton, 2006a; Soden et al., 2008). Rising temperature globally is expected to increase the horizontal latent heat transport by the atmosphere into the Arctic (Flannery, 1984; Alexeev et al., 2005; Cai, 2005; Langen and Alexeev, 2007; Kug et al., 2010), which warms primarily the lower troposphere. On average, CMIP3 models simulate enhanced latent heat transport (Held and Soden, 2006), but north of about 65°N, the sensible heat transport declines enough to more than offset the latent heat transport increase (Hwang et al., 2011). Increased atmospheric heat transport into the Arctic and subsidence warming has been associated with a teleconnection driven by enhanced convection in the tropical western Pacific (Lee et al., 2011). Ocean heat transport plays a role in the simulated Arctic amplification, with both large late 20th century transport (Mahlstein and Knutti, 2011) and increases over the 21st century (Hwang et al., 2011; Bitz et al., 2012) associated with higher amplification. As noted by Held and Soden (2006), Kay et al. (2012), and Alexeev and Jackson (2012), diagnosing the role of various factors in amplified warming is complicated by coupling in the system in which local feedbacks interact with poleward heat transports.

Although models consistently exhibit Arctic amplification as global mean temperatures rise, the multitude of physical processes described above mean that they differ considerably in the magnitude. Previous work has implicated variations across climate models in numerous factors including inversion strength (Boé et al., 2009a), ocean heat transport (Holland and Bitz, 2003; Mahlstein and Knutti, 2011), albedo feedback (Winton, 2006a), longwave radiative feedbacks (Winton, 2006a) and shortwave cloud feedback (Crook et al., 2011; Kay et al., 2012) as playing a role in the across-model scatter in polar amplification. The magnitude of amplification is generally higher in models with less extensive late 20th century sea ice in June, suggesting that the initial ice state influences the 21st century Arctic amplification. The pattern of simulated Arctic warming is also associated with the initial ice state, and in particular with the location of the winter sea ice edge (Holland and Bitz, 2003; Räisänen, 2007; Bracegirdle and Stephenson, 2012). This relationship has been suggested as a constraint on projected Arctic warming (Abe et al., 2011; Bracegirdle and Stephenson, 2012), although, in general, the ability of models to reproduce observed climate and its trends is not a sufficient condition for attributing *high confidence* to the projection of future trends (see Section 9.8).

Minima in surface warming occur in the North Atlantic and Southern Oceans under transient forcing in part due to deep ocean mixed layers in those regions (Manabe et al., 1990; Xie et al., 2010). Trenberth and Fasullo (2010) find that the large biases in the Southern Ocean energy budget in CMIP3 coupled models negatively correlate with equilibrium climate sensitivity (see Section 12.5.3), suggesting that an improved mean state in the Southern Ocean is needed before warming there can be understood. In the equatorial Pacific, warming is enhanced in a narrow band which previous assessments have described as 'El Niño-like', as may be expected from the projected decrease in atmospheric tropical circulations (see Section 12.4.4). However, DiNezio et al. (2009) highlight that the tropical Pacific warming in the CMIP3 models is not 'El Niño-like' as the pattern of warming and associated teleconnections (Xie et al., 2010; Section 12.4.5.2) is quite distinct from that of an El Niño event. Instead the pattern is of enhanced equatorial warming and is due to a meridional minimum in evaporative damping on the equator (Liu et al., 2005) and ocean dynamical changes that can be decoupled from atmospheric changes (DiNezio et al., 2009) (see also further discussion in Section 12.4.7).

In summary, there is robust evidence over multiple generations of models and *high confidence* in these large-scale warming patterns. In the absence of a strong reduction in the Atlantic Meridional Overturning Circulation (AMOC), there is *very high confidence* that the Arctic region is projected to warm most.

12.4.3.2 Zonal Average Atmospheric Temperature

Zonal temperature changes at the end of the 21st century show warming throughout the troposphere and, depending on the scenario, a mix of warming and cooling in the stratosphere (Figure 12.12). The maximum warming in the tropical upper troposphere is consistent with theoretical explanations and associated with a decline in the moist adiabatic lapse rate of temperature in the tropics as the climate warms (Bony et al., 2006). The northern polar regions also experience large warming in the lower atmosphere, consistent with the mechanisms discussed in Section 12.4.3.1. The tropospheric patterns are similar to those in the TAR and AR4 with the RCP8.5 changes being up to several degrees warmer in the tropics compared to the A1B changes appearing in the AR4. Similar tropospheric patterns appear in the RCP 2.6 and 4.5 changes, but with reduced magnitudes, suggesting some degree of scaling with forcing change in the troposphere, similar to behaviour discussed in the AR4 and Section 12.4.2. The consistency of tropospheric patterns over multiple generations of models indicates *high confidence* in these projected changes.

In the stratosphere, the models show similar tropical patterns of change, with magnitudes differing according to the degree of climate forcing. Substantial differences appear in polar regions. In the north, RCP8.5 and 4.5 yield cooling, though it is more significant in the RCP8.5 ensemble. In contrast, RCP2.6 shows warming, albeit weak and with little significance. In the southern polar region, RCP 2.6 and 4.5 both show significant warming, and RCP8.5 is the outlier, with significant cooling. The polar stratospheric warming, especially in the SH, is similar to that found by Butchart et al. (2010) and Meehl et al. (2012) in GCM simulations that showed effects of ozone recovery in determining the patterns (Baldwin et al., 2007; Son et al., 2010). Eyring et al. (2013) find behaviour in the CMIP5 ensemble both for models with and without interactive chemistry that supports the contention that the polar stratospheric changes in Figure 12.12 are strongly influenced by ozone recovery. Overall, the stratospheric temperature changes do not exhibit pattern scaling with global temperature change and are dependent on ozone recovery.

Away from the polar stratosphere, there is physical and pattern consistency in temperature changes between different generations of models assessed here and in the TAR and AR4. The consistency is especially clear in the northern high latitudes and, coupled with physical understanding, indicates that some of the greatest warming is *very likely* to occur here. There is also consistency across generations of models in relatively large warming in the tropical upper troposphere. Allen and Sherwood (2008) and Johnson and Xie (2010) have presented dynamic and thermodynamic arguments, respectively, for the physical robustness of the tropical behaviour. However, there remains uncertainty about the magnitude of warming simulated in the tropical upper troposphere because large observational uncertainties and contradictory analyses limit a confident assessment of model accuracy in simulating temperature trends in the tropical upper troposphere (Section 9.4.1.4.2). The combined evidence indicates that relatively large warming in the tropical upper troposphere is *likely*, but with *medium confidence*.

12.4.3.3 Temperature Extremes

As the climate continues to warm, changes in several types of temperature extremes have been observed (Donat et al., 2013), and are expected to continue in the future in concert with global warming (Seneviratne et al., 2012). Extremes occur on multiple time scales, from a single day or a few consecutive days (a heat wave) to monthly and seasonal events. Extreme temperature events are often defined by indices (see Box 2.4 for the common definitions used), for example, percentage of days in a year when maximum temperature is above the 90th percentile of a present day distribution or by long period return values. Although changes in temperature extremes are a very robust

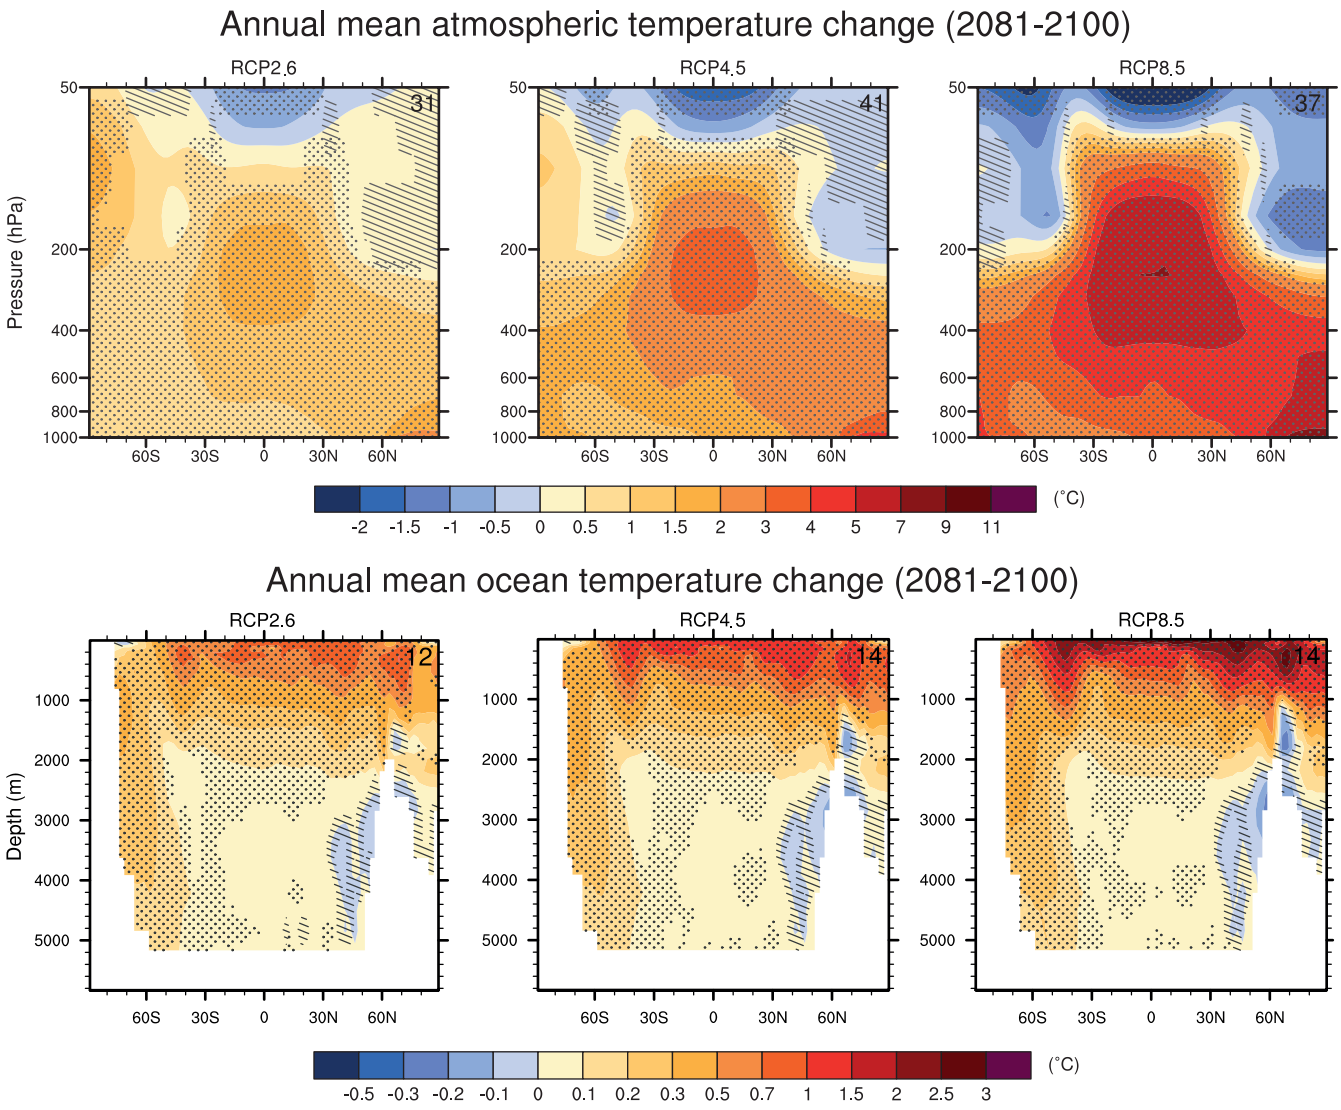

Figure 12.12 | CMIP5 multi-model changes in annual mean zonal mean temperature in the atmosphere and ocean relative to 1986–2005 for 2081–2100 under the RCP2.6 (left), RCP4.5 (centre) and RCP8.5 (right) forcing scenarios. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model change mean is greater than two standard deviations of internal variability and where at least 90% of the models agree on the sign of change (see Box 12.1).

signature of anthropogenic climate change (Seneviratne et al., 2012), the magnitude of change and consensus among models varies with the characteristics of the event being considered (e.g., time scale, magnitude, duration and spatial extent) as well as the definition used to describe the extreme.

Since the AR4 many advances have been made in establishing global observed records of extremes (Alexander et al., 2006; Perkins et al., 2012; Donat et al., 2013) against which models can be evaluated to give context to future projections (Sillmann and Roeckner, 2008; Alexander and Arblaster, 2009). Numerous regional assessments of future changes in extremes have also been performed and a comprehensive summary of these is given in Seneviratne et al. (2012). Here we summarize the key findings from this report and assess updates since then.

It is *virtually certain* that there will be more hot and fewer cold extremes as global temperature increases (Caesar and Lowe, 2012; Orlowsky and Seneviratne, 2012; Sillmann et al., 2013), consistent with previous assessments (Solomon et al., 2007; Seneviratne et al., 2012). Figure 12.13 shows multi-model mean changes in the absolute temperature indices of the coldest day of the year and the hottest day of the year and the threshold-based indices of frost days and tropical nights from the CMIP5 ensemble (Sillmann et al., 2013). A robust increase in warm temperature extremes and decrease in cold temperature extremes is found at the end of the 21st century, with the magnitude of the changes increasing with increased anthropogenic forcing. The coldest night of the year undergoes larger increases than the hottest day in the globally averaged time series (Figure 12.13b and d). This tendency is consistent with the CMIP3 model results shown in Figure 12.13, which use different models and the SRES scenarios (see Seneviratne et al. (2012) for earlier CMIP3 results). Similarly, increases in the frequency of warm nights are greater than increases in the frequency of warm days (Sillmann et al., 2013). Regionally, the largest increases in the coldest night of the year are projected in the high latitudes of

the NH under the RCP8.5 scenario (Figure 12.13a). The subtropics and mid-latitudes exhibit the greatest projected changes in the hottest day of the year, whereas changes in tropical nights and the frequency of warm days and warm nights are largest in the tropics (Sillmann et al., 2013). The number of frost days declines in all regions while significant increases in tropical nights are seen in southeastern North America, the Mediterranean and central Asia.

It is *very likely* that, on average, there will be more record high than record cold temperatures in a warmer average climate. For example, Meehl et al. (2009) find that the current ratio of 2 to 1 for record daily high maxima to low minima over the USA becomes approximately 20 to 1 by the mid-21st century and 50 to 1 by late century in their model simulation of the SRES A1B scenario. However, even at the end of the century daily record low minima continue to be broken, if in a small number, consistent with Kodra et al. (2011), who conclude that cold extremes will continue to occur in a warmer climate, even though their frequency will decline.

It is also *very likely* that heat waves, defined as spells of days with temperature above a threshold determined from historical climatology, will occur with a higher frequency and duration, mainly as a direct consequence of the increase in seasonal mean temperatures (Barnett et al., 2006; Ballester et al., 2010a, 2010b; Fischer and Schär, 2010). Changes in the absolute value of temperature extremes are also *very likely* and expected to regionally exceed global temperature increases by far, with substantial changes in hot extremes projected even for moderate (<2.5°C above present day) average warming levels (Clark et al., 2010; Diffenbaugh and Ashfaq, 2010). These changes often differ from the mean temperature increase, as a result of changes in variability and shape of the temperature distribution (Hegerl et al., 2004; Meehl and Tebaldi, 2004; Clark et al., 2006). For example, summer temperature extremes over central and southern Europe are projected to warm substantially more than the corresponding mean local temperatures as a result of enhanced temperature variability at interannual to intraseasonal time scales (Schär et al., 2004; Clark et al., 2006; Kjellstrom et al., 2007; Vidale et al., 2007; Fischer and Schär, 2009, 2010; Nikulin et al., 2011; Fischer et al., 2012a). Several recent studies have also argued that the probability of occurrence of a Russian heat wave at least as severe as the one in 2010 increases substantially (by a factor of 5 to 10 by the mid-century) along with increasing mean temperatures and enhanced temperature variability (Barriopedro et al., 2011; Dole et al., 2011).

Since the AR4, an increased understanding of mechanisms and feedbacks leading to projected changes in extremes has been gained (Seneviratne et al., 2012). Climate models suggest that hot extremes are amplified by soil moisture-temperature feedbacks (Seneviratne et al., 2006; Diffenbaugh et al., 2007; Lenderink et al., 2007; Vidale et al., 2007; Fischer and Schär, 2009; Fischer et al., 2012a) in northern mid-latitude regions as the climate warms, consistent with previous assessments. Changes in temperature extremes may also be impacted by changes in land–sea contrast, with Watterson et al. (2008) showing an amplification of southern Australian summer warm extremes over the mean due to anomalous temperature advection from warmer continental interiors. The largest increases in the magnitude of warm extremes are simulated over mid-latitude continental areas, consistent with the drier conditions, and the associated reduction in evaporative cooling from the land surface projected over these areas (Kharin et al., 2007). The representation of the latter constitutes a major source of model uncertainty for projections of the absolute magnitude of temperature extremes (Clark et al., 2010; Fischer et al., 2011).

Winter cold extremes also warm more than the local mean temperature over northern high latitudes (Orlowsky and Seneviratne, 2012; Sillmann et al., 2013) as a result of reduced temperature variability related to declining snow cover (Gregory and Mitchell, 1995; Kjellstrom et al., 2007; Fischer et al., 2011) and decreases in land–sea contrast (de Vries et al., 2012). Changes in atmospheric circulation, induced by remote surface heating can also modify the temperature distribution (Haarsma et al., 2009). Sillmann and Croci-Maspoli (2009) note that cold winter extremes over Europe are in part driven by atmospheric blocking and changes to these blocking patterns in the future lead to changes in the frequency and spatial distribution of cold temperature extremes as global temperatures increase. Occasional cold winters will continue to occur (Räisänen and Ylhaisi, 2011).

Human discomfort, morbidity and mortality during heat waves depend not only on temperature but also specific humidity. Heat stress, defined as the combined effect of temperature and humidity, is expected to increase along with warming temperatures and dominates the local decrease in summer relative humidity due to soil drying (Diffenbaugh et al., 2007; Fischer et al., 2012b; Dunne et al., 2013). Areas with abundant atmospheric moisture availability and high present-day temperatures such as Mediterranean coastal regions are expected to experience the greatest heat stress changes because the heat stress response scales with humidity which thus becomes increasingly important to heat stress at higher temperatures (Fischer and Schär, 2010; Sherwood and Huber, 2010; Willett and Sherwood, 2012). For some regions, simulated heat stress indicators are remarkably robust, because those models with stronger warming simulate a stronger decrease in atmospheric relative humidity (Fischer and Knutti, 2013).

Changes in rare temperature extremes can be assessed using extreme value theory based techniques (Seneviratne et al., 2012). Kharin et al. (2007), in an analysis of CMIP3 models, found large increases in the 20-year return values of the annual maximum and minimum daily averaged surface air temperatures (i.e., the size of an event that would be expected on average once every 20 years, or with a 5% chance every year) with larger changes over land than ocean. Figure 12.14 displays the end of 21st century change in the magnitude of these rare events from the CMIP5 models in the RCP2.6, 4.5 and 8.5 scenarios (Kharin et al., 2013). Comparison to the changes in summer mean temperature shown in Figure AI.5 and A1.7 of Annex I Supplementary Material reveals that rare high temperature events are projected to change at rates similar to or slightly larger than the summertime mean temperature in many land areas. However, in much of Northern Europe 20-year return values of daily high temperatures are projected to increase 2°C or more than JJA mean temperatures under RCP8.5, consistent with previous studies (Sterl et al., 2008; Orlowsky and Seneviratne, 2012). Rare low temperature events are projected to experience significantly larger increases than the mean in most land regions, with a pronounced effect at high latitudes. Twenty-year return values of cold extremes increase significantly more than

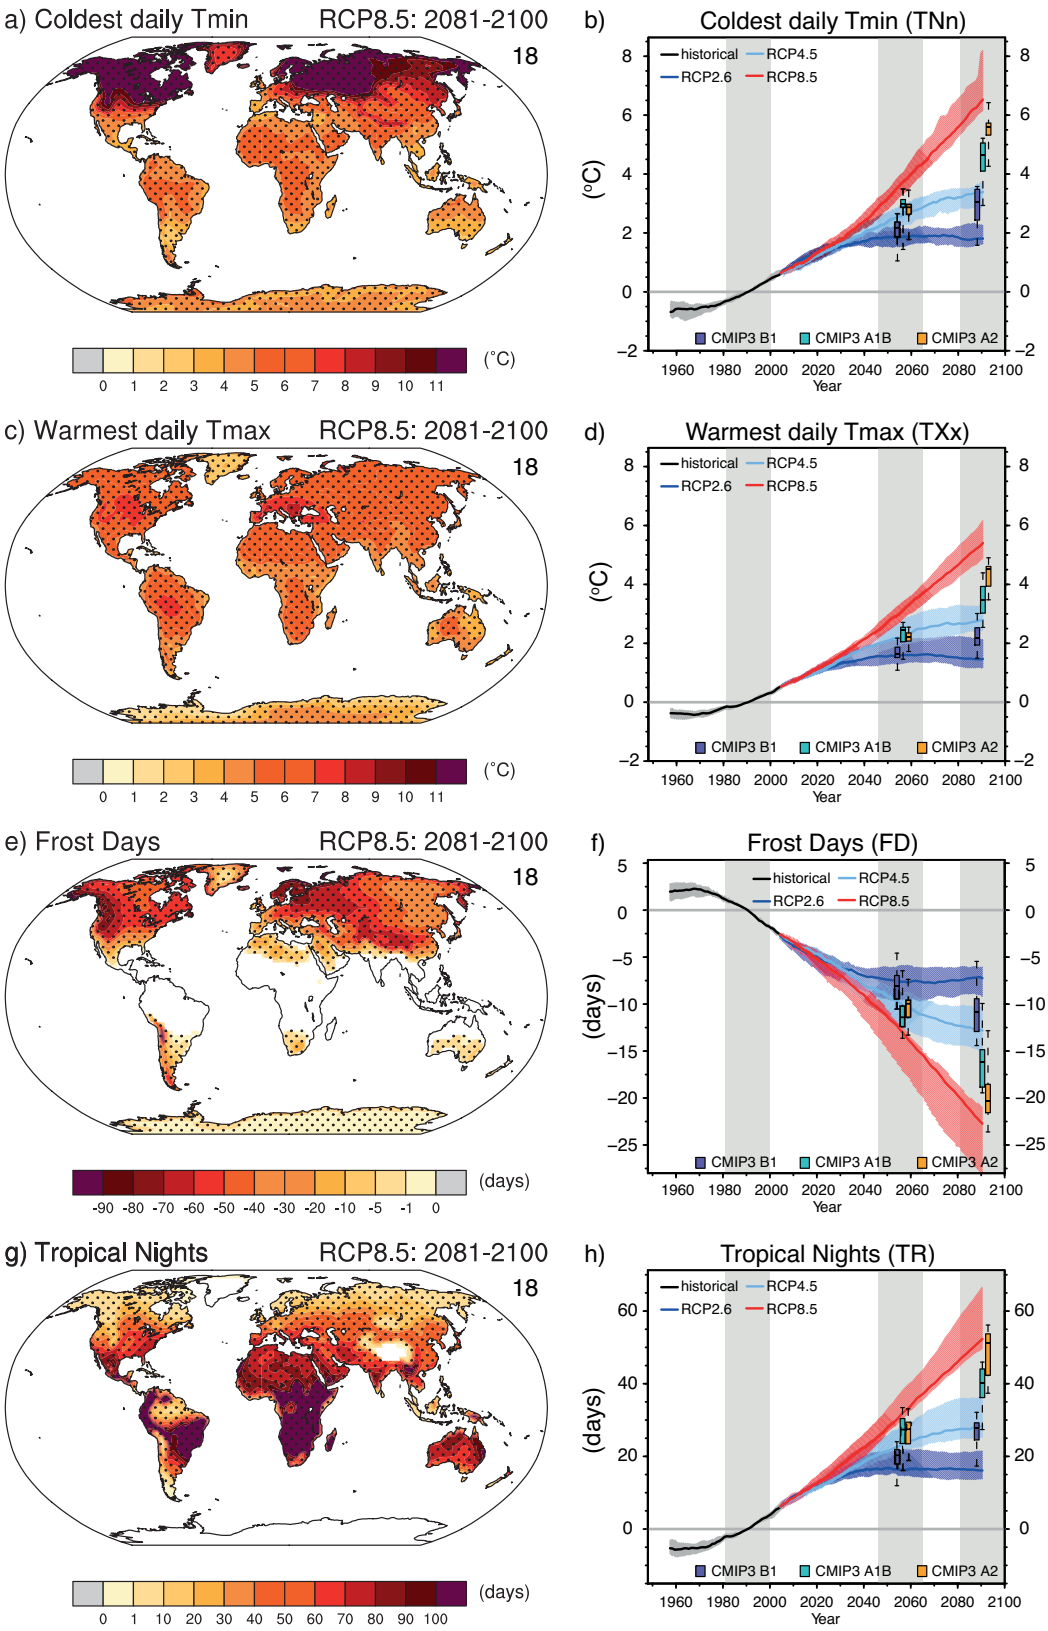

Figure 12.13 | CMIP5 multi-model mean geographical changes (relative to a 1981–2000 reference period in common with CMIP3) under RCP8.5 and 20-year smoothed time series for RCP2.6, RCP4.5 and RCP8.5 in the (a, b) annual minimum of daily minimum temperature, (c, d) annual maximum of daily maximum temperature, (e, f) frost days (number of days below 0°C) and (g, h) tropical nights (number of days above 20°C). White areas over land indicate regions where the index is not valid. Shading in the time series represents the interquartile ensemble spread (25th and 75th quantiles). The box-and-whisker plots show the interquartile ensemble spread (box) and outliers (whiskers) for 11 CMIP3 model simulations of the SRES scenarios A2 (orange), A1B (cyan), and B1 (purple) globally averaged over the respective future time periods (2046–2065 and 2081–2100) as anomalies from the 1981–2000 reference period. Stippling indicates grid points with changes that are significant at the 5% level using a Wilcoxon signed-ranked test. (Updated from Sillmann et al. (2013), excluding the FGOALS-s2 model.)

winter mean temperature changes, particularly over parts of North America and Europe. Kharin et al. (2013) concluded from the CMIP5 models that it is *likely* that in most land regions a current 20 year maximum temperature event is projected to become a one-in-two-year event by the end of the 21st century under the RCP4.5 and RCP8.5 scenarios, except for some regions of the high latitudes of the NH where it is *likely* to become a one-in-five-year event (see also Seneviratne et al. (2012) Figure 3.5). Current 20-year minimum temperature events are projected to become exceedingly rare, with return periods *likely* increasing to more than 100 years in almost all locations under RCP8.5 (Kharin et al., 2013). Section 10.6.1.1 notes that a number of detection and attribution studies since SREX suggest that the model changes may tend to be too large for warm extremes and too small for cold extremes and thus these likelihood statements are somewhat less strongly stated than a direct interpretation of model output and its ranges. The CMIP5 analysis shown in Figure 12.14 reinforces this assessment of large changes in the frequency of rare events, particularly in the RCP8.5 scenario (Kharin et al., 2013).

There is high consensus among models in the sign of the future change in temperature extremes, with recent studies confirming this conclusion from the previous assessments (Tebaldi et al., 2006; Meehl et al., 2007b; Orlowsky and Seneviratne, 2012; Seneviratne et al., 2012; Sillmann et al., 2013). However, the magnitude of the change remains uncertain owing to scenario and model (both structural and parameter) uncertainty (Clark et al., 2010) as well as internal variability. These uncertainties are much larger than corresponding uncertainties in the magnitude of mean temperature change (Barnett et al., 2006; Clark et al., 2006; Fischer and Schär, 2010; Fischer et al., 2011).

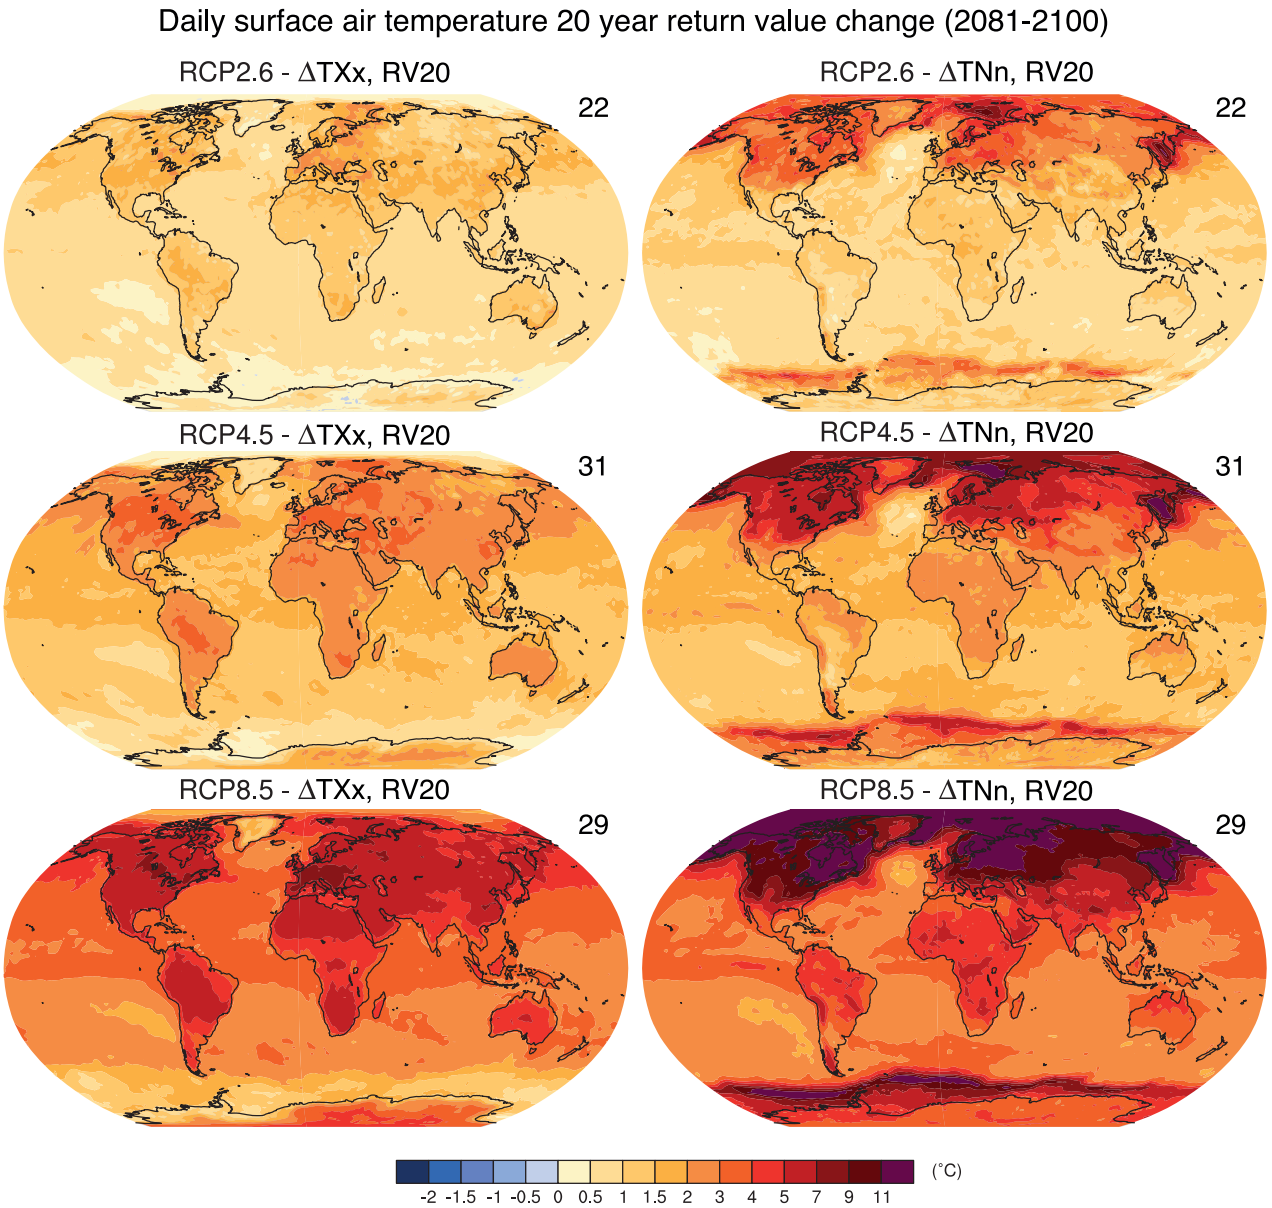

Figure 12.14 | The CMIP5 multi-model median change in 20-year return values of annual warm temperature extremes (left-hand panels) and cold temperature extremes (right-hand panels) as simulated by CMIP5 models in 2081–2100 relative to 1986–2005 in the RCP2.6 (top), RCP4.5 (middle panels), and RCP8.5 (bottom) experiments.

12.4.3.4 Energy Budget

Anthropogenic or natural perturbations to the climate system produce RFs that result in an imbalance in the global energy budget at the top of the atmosphere (TOA) and affect the global mean temperature (Section 12.3.3). The climate responds to a change in RF on multiple time scales and at multiyear time scales the energy imbalance (i.e., the energy heating or cooling the Earth) is very close to the ocean heat uptake due to the much lower thermal inertia of the atmosphere and the continental surfaces (Levitus et al., 2005; Knutti et al., 2008a; Murphy et al., 2009; Hansen et al., 2011). The radiative responses of the fluxes at TOA are generally analysed using the forcing-feedback framework and are presented in Section 9.7.2.

CMIP5 models simulate a small increase of the energy imbalance at the TOA over the 20th century (see Box 3.1, Box 9.2 and Box 13.1). The future evolution of the imbalance is very different depending on the scenario (Figure 12.15a): for RCP8.5 it continues to increase rapidly, much less for RCP6.0, it is almost constant for RCP4.5 and decreases for RCP2.6. This latter negative trend reveals the quasi-stabilization characteristic of RCP2.6. (In a transient scenario simulation, the TOA imbalance is always less than the RF because of the slow rate of ocean heat uptake.)

The rapid fluctuations that are simulated during the 20th century originate from volcanic eruptions that are prescribed in the models (see Section 12.3.2). These aerosols reflect solar radiation and thus decrease the amount of SW radiation absorbed by the Earth (Figure 12.15c). The minimum of shortwave (SW) radiation absorbed by the Earth during the period 1960–2000 is due mainly to two factors: a sequence of volcanic eruptions and an increase of the reflecting aerosol burden due to human activities (see Sections 7.5, 8.5 and 9.4.6). During the 21st century, the absorbed SW radiation monotonically increases for the RCP8.5 scenario, and increases and subsequently stabilizes for the other scenarios, consistent with what has been previously obtained with CMIP3 models and SRES scenarios (Trenberth and Fasullo, 2009). The two main contributions to the SW changes are the change of clouds (see Section 12.4.3.5) and the change of the cryosphere (see Section 12.4.6) at high latitudes. In the longwave (LW) domain (Figure 12.15b), the net flux at TOA represents the opposite of the flux that is emitted by the Earth's surface and atmosphere toward space, i.e., a negative anomaly represents an increase of the emitted

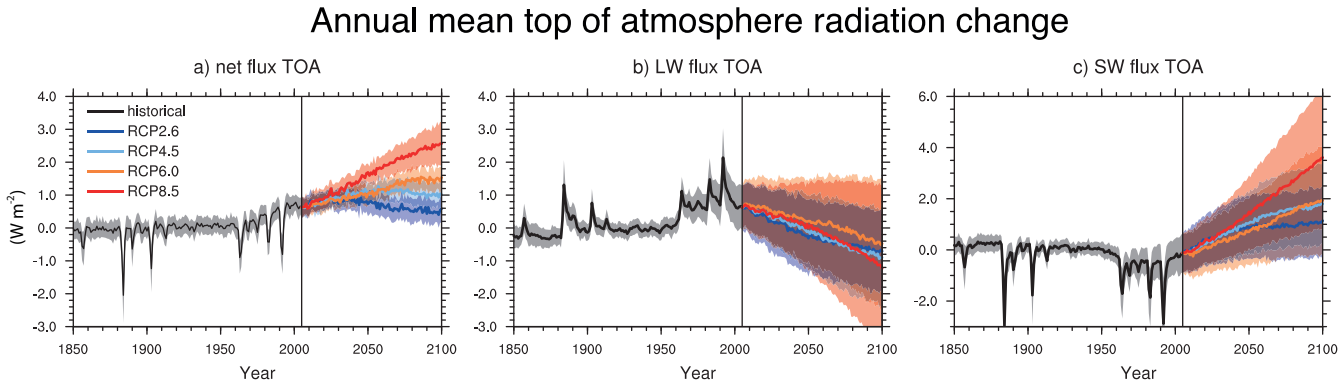

Figure 12.15 | Time series of global and annual multi-model mean (a) net total radiation anomaly at the top of the atmosphere (TOA), (b) net longwave radiation anomaly at the TOA and (c) net shortwave radiation anomaly at the TOA from the CMIP5 concentration-driven experiments for the historical period (black) and the four RCP scenarios. All the fluxes are positive downward and units are W m^{-2}. The anomalies are calculated relative to the 1900–1950 base period as this is a common period to all model experiments with few volcanic eruptions and relatively small trends. One ensemble member is used for each individual CMIP5 model and the ± standard deviation across the distribution of individual models is shaded.

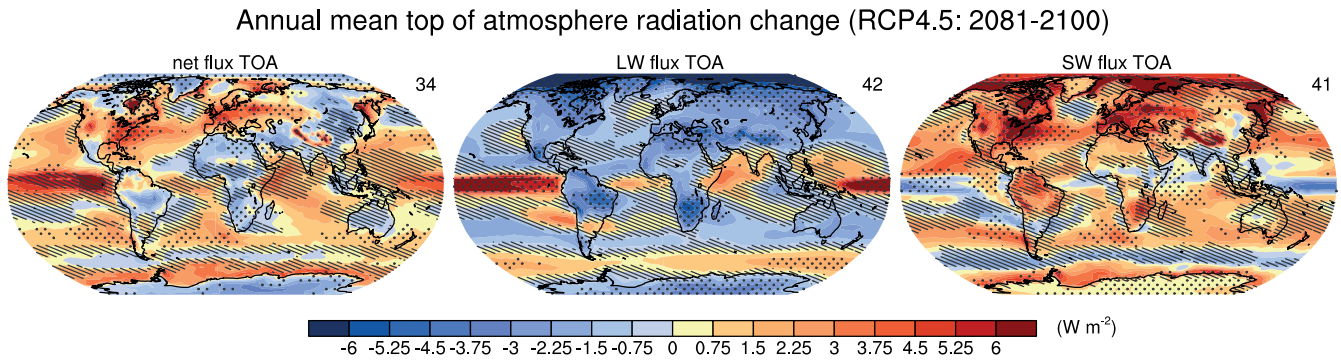

Figure 12.16 | Multi-model CMIP5 average changes in annual mean (left) net total radiation anomaly at the top of the atmosphere (TOA), (middle) net longwave radiation anomaly at the TOA and (right) net shortwave radiation anomaly at the TOA for the RCP4.5 scenario averaged over the periods 2081–2100. All fluxes are positive downward, units are W m^{-2}. The net radiation anomalies are computed with respect to the 1900–1950 base period. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of models agree on the sign of change (see Box 12.1).

LW radiation. The LW net flux depends mainly on two factors: the surface temperature and the magnitude of the greenhouse effect of the atmosphere. During the 20th century, the rapid fluctuations of LW radiation are driven by volcanic forcings, which decrease the absorbed SW radiation, surface temperature, and the LW radiation emitted by the Earth toward space. During the period 1960–2000, the fast increase of GHG concentrations also decreases the radiation emitted by the Earth. In response to this net heating of the Earth, temperatures warm and thereby increase emitted LW radiation although the change of the temperature vertical profile, water vapour, and cloud properties modulate this response (e.g., Bony et al., 2006; Randall et al., 2007).

12.4.3.5 Clouds

This section provides a summary description of future changes in clouds and their feedbacks on climate. A more general and more precise description and assessment of the role of clouds in the climate system is provided in Chapter 7, in particular Section 7.2 for cloud processes and feedbacks and Section 7.4 for aerosol–cloud interactions. Cloud feedbacks and adjustments are presented in Section 7.2.5 and a synthesis is provided in Section 7.2.6. Clouds are a major component of the climate system and play an important role in climate sensitivity (Cess et al., 1990; Randall et al., 2007), the diurnal temperature range (DTR) over land (Zhou et al., 2009), and land–sea contrast (see Section 12.4.3.1). The observed global mean cloud RF is about –20 W m^{-2} (Loeb et al., 2009) (see Section 7.2.1), that is, clouds have a net cooling effect. Current GCMs simulate clouds through various complex parameterizations (see Section 7.2.3), and cloud feedback is a major source of the spread of the climate sensitivity estimate (Soden and Held, 2006; Randall et al., 2007; Dufresne and Bony, 2008) (see Section 9.7.2).

Under future projections the multi-model pattern of total cloud amount shows consistent decreases in the subtropics, in conjunction with a decrease of the relative humidity there, and increases at high latitudes. Another robust pattern is an increase in cloud cover at all latitudes in the vicinity of the tropopause, a signature of the increase of the altitude of high level clouds in convective regions (Wetherald and Manabe, 1988; Meehl et al., 2007b; Soden and Vecchi, 2011; Zelinka et al., 2012). Low-level clouds were identified as a primary cause of inter-model spread in cloud feedbacks in CMIP3 models (Bony and Dufresne, 2005; Webb et al., 2006; Wyant et al., 2006). Since AR4, these results have been confirmed along with the positive feedbacks due to high level clouds in the CMIP3 or CFMIP models (Zelinka and Hartmann, 2010; Soden and Vecchi, 2011; Webb et al., 2013) and CMIP5 models (Vial et al., 2013). Since AR4, the response of clouds has been partitioned in a direct or 'rapid' response of clouds to CO_2 and a 'slow' response of clouds to the surface temperature increase (i.e., the usual feedback response) (Gregory and Webb, 2008). The radiative effect of clouds depends mainly on their fraction, optical depth and temperature. The contribution of these variables to the cloud feedback has been quantified for the multi-model CMIP3 (Soden and Vecchi, 2011) and CFMIP1 database (Zelinka et al., 2012). These findings are consistent with the radiative changes obtained with the CMIP5 models (Figure 12.16) and may be summarized as follows (see Section 7.2.5 for more details).

The dominant contributor to the SW cloud feedback is the change in cloud fraction. The reduction of cloud fraction between 50°S and 50°N, except along the equator and the eastern part of the ocean basins (Figure 12.17), contributes to an increase in the absorbed solar radiation (Figure 12.16c). Physical mechanisms and the role of different parameterizations have been proposed to explain this reduction of low-level clouds (Zhang and Bretherton, 2008; Caldwell and Bretherton, 2009; Brient and Bony, 2013; Webb et al., 2013). Poleward of 50°S, the cloud fraction and the cloud optical depth increases, thereby increasing cloud reflectance. This leads to a decrease of solar absorption around Antarctica where the ocean is nearly ice free in summer (Figure 12.16c). However, there is *low confidence* in this result because GCMs do not reproduce the nearly 100% cloud cover observed there and the negative feedback could be overestimated (Trenberth and Fasullo, 2010) or, at the opposite, underestimated because the cloud optical depth simulated by models is biased high there (Zelinka et al., 2012).

In the LW domain, the tropical high cloud changes exert the dominant effect. A lifting of the cloud top with warming is simulated consistently across models (Meehl et al., 2007b) which leads to a positive feedback whereby the LW emissions from high clouds decrease as they cool (Figure 12.16b). The dominant driver of this effect is the increase of tropopause height and physical explanations have been proposed (Hartmann and Larson, 2002; Lorenz and DeWeaver, 2007; Zelinka

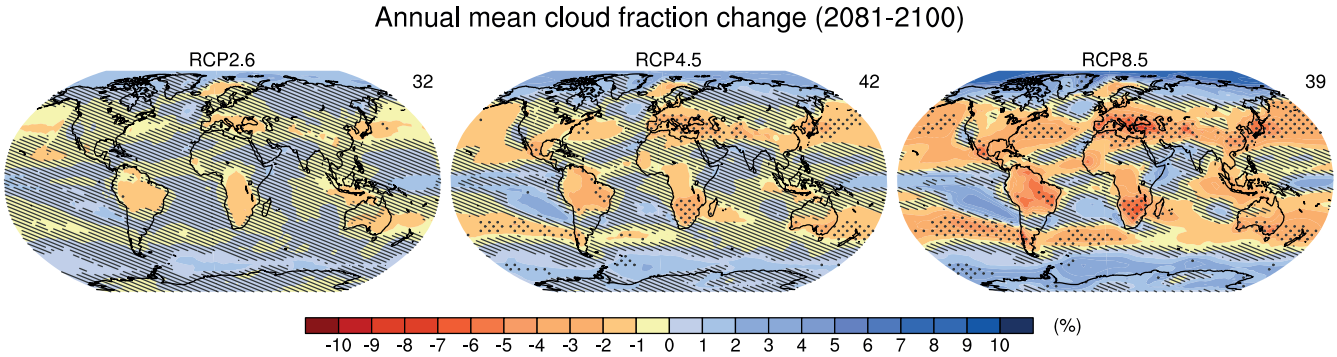

Figure 12.17 | CMIP5 multi-model changes in annual mean total cloud fraction (in %) relative to 1986–2005 for 2081–2100 under the RCP2.6 (left), RCP4.5 (centre) and RCP8.5 (right) forcing scenarios. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

and Hartmann, 2010). Although the decrease in cloudiness generally increases outgoing longwave radiation and partly offsets the effect of cloud rising, the net effect is a consistent positive global mean LW cloud feedback across CMIP and CFMIP models. Global mean SW cloud feedbacks range from slightly negative to strongly positive (Soden and Vecchi, 2011; Zelinka et al., 2012), with an inter-model spread in net cloud feedback being mainly attributable to low-level cloud changes.

In summary, both the multi-model mean and the inter-model spread of the cloud fraction and radiative flux changes simulated by the CMIP5 models are consistent with those previously obtained by the CMIP3 models. These include decreases in cloud amount in the subtropics, increases at high latitudes and increases in the altitude of high level clouds in convective regions. Many of these changes have been understood primarily as responses to large-scale circulation changes (see Section 7.2.6).

12.4.4 Changes in Atmospheric Circulation

Projected changes in energy and water cycles couple with changes in atmospheric circulation and mass distribution. Understanding this coupling is necessary to assess physical behaviour underlying projected changes, particularly at regional scales, revealing why changes occur and the realism of the changes. The focus in this section is on atmospheric circulation behaviour that CMIP5 GCMs resolve well. Thus, the section includes discussion of extratropical cyclones but not tropical cyclones: extratropical cyclones are fairly well resolved by most CMIP5 GCMs, whereas tropical cyclones are not, requiring resolutions finer than used by the large majority of CMIP5 GCMs (see Section 9.5.4.3). Detailed discussion of tropical cyclones appears in Section 14.6.1 (see also Section 11.3.2.5.3 for near term changes and Section 3.4.4 in Seneviratne et al. (2012)). Regional detail concerning extratropical storm tracks, including causal processes, appears in Section 14.6.2 (see also Section 11.3.2.4 for near-term changes and Seneviratne et al. (2012) for an assessment of projected changes related to weather and climate extremes).

12.4.4.1 Mean Sea Level Pressure and Upper-Air Winds

Sea level pressure gives an indication of surface changes in atmospheric circulation (Figure 12.18). As in previous assessments, a robust feature of the pattern of change is a decrease in high latitudes and increases in the mid-latitudes, associated with poleward shifts in the SH mid-latitude storm tracks (Section 12.4.4.3) and positive trends in the annular modes (Section 14.5) as well as an expansion of the Hadley Cell (Section 12.4.4.2). Similar patterns of sea level pressure change are found in observed trends over recent decades, suggesting an already detectable change (Gillett and Stott, 2009; Section 10.3.3.4), although the observed patterns are influenced by both natural and anthropogenic forcing as well as internal variability and the relative importance of these influences is likely to change in the future. Internal variability has been found to play a large role in uncertainties of future sea level pressure projections, particularly at higher latitudes (Deser et al., 2012a).

In boreal winter, decreases of sea level pressure over NH high latitudes are slightly weaker in the CMIP5 ensemble compared to previous assessments, consistent with Scaife et al. (2012) and Karpechko and Manzini (2012), who suggest that improvements in the representation of the stratosphere can influence this pattern. In austral summer, the SH projections are impacted by the additional influence of stratospheric ozone recovery (see Section 11.3.2.4.2) which opposes changes due to GHGs. Under the weaker GHG emissions of RCP2.6, decreases in sea level pressure over the SH mid-latitudes and increases over SH high latitudes are consistent with expected changes from ozone recovery (Arblaster et al., 2011; McLandress et al., 2011; Polvani et al., 2011). For

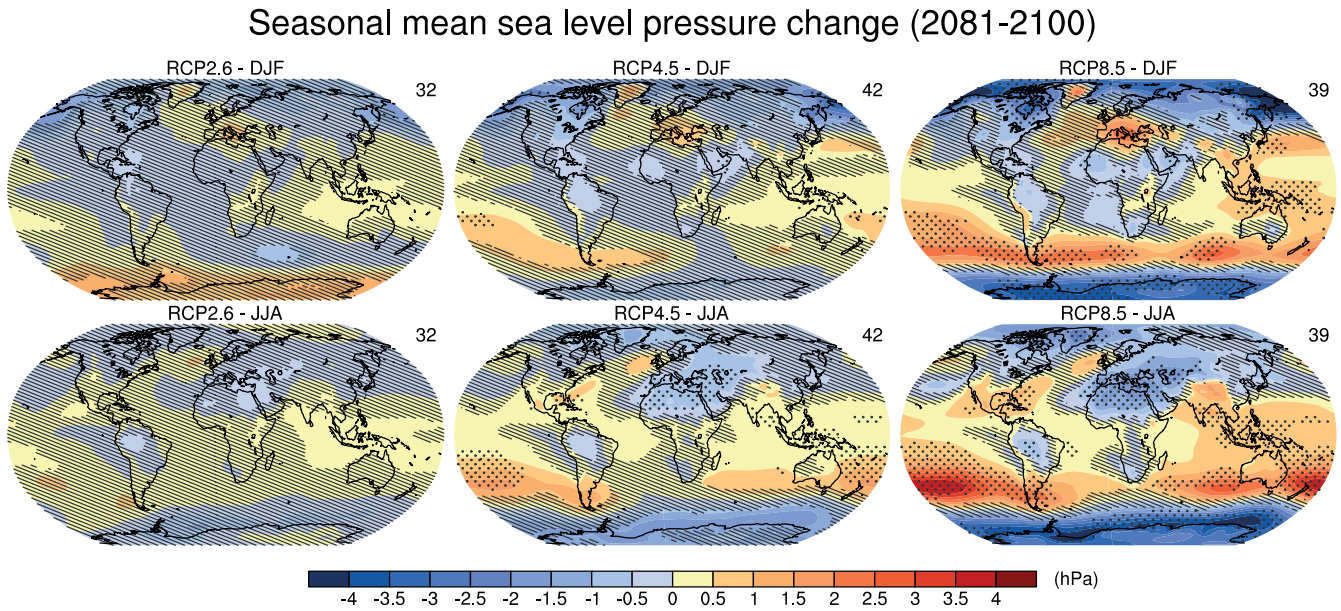

Figure 12.18 | CMIP5 multi-model ensemble average of December, January and February (DJF, top row) and June, July and August (JJA, bottom row) mean sea level pressure change (2081–2100 minus 1986–2005) for, from left to right, RCP2.6, 4.5 and 8.5. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of models agree on the sign of change (see Box 12.1).

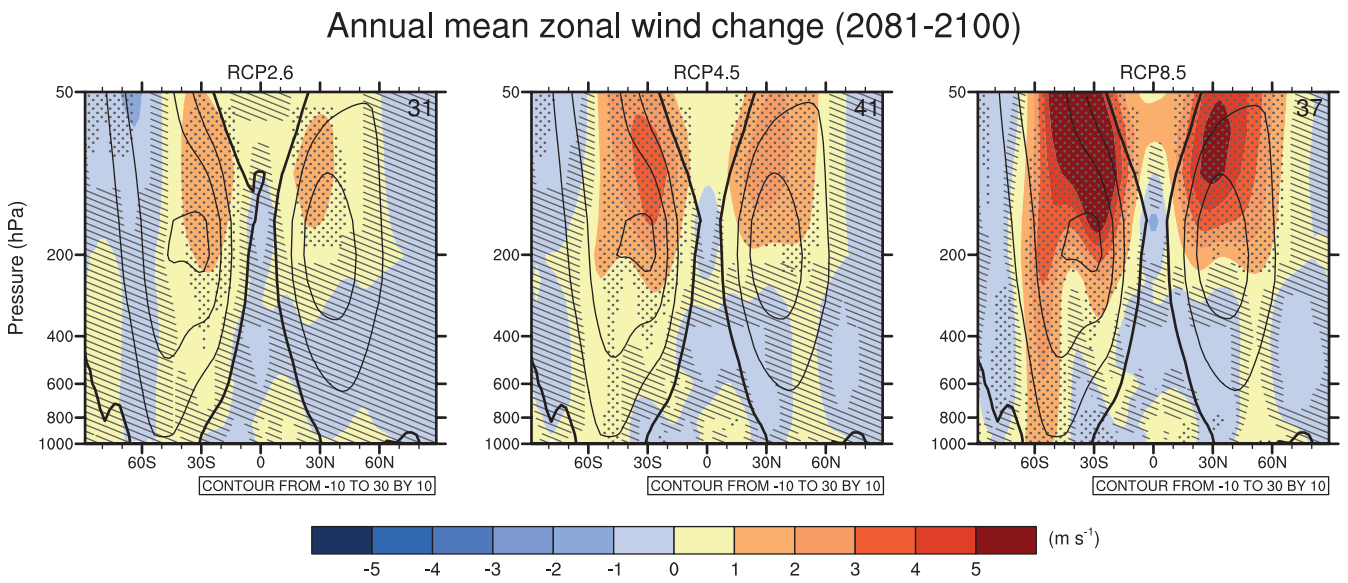

Figure 12.19 | Coupled Model Intercomparison Project Phase 5 (CMIP5) multi-model ensemble average of zonal and annual mean wind change (2081–2100 minus 1986–2005) for, from left to right, Representative Concentration Pathway 2.6 (RCP2.6), 4.5 and 8.5. Black contours represent the multi-model average for the 1986–2005 base period. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of models agree on the sign of change (see Box 12.1).

all other RCPs, the magnitude of SH extratropical changes scales with the RF, as found in previous model ensembles (Paeth and Pollinger, 2010; Simpkins and Karpechko, 2012).

Large increases in seasonal sea level pressure are also found in regions of sub-tropical drying such as the Mediterranean and northern Africa in DJF and Australia in JJA. Projected changes in the tropics are less consistent across the models; however, a decrease in the eastern equatorial Pacific and increase over the maritime continent, associated with a weakening of the Walker Circulation (Vecchi and Soden, 2007; Power and Kociuba, 2011b), is found in all RCPs.

Future changes in zonal and annual mean zonal winds (Figure 12.19) are seen throughout the atmosphere with stronger changes in higher RCPs. Large increases in winds are evident in the tropical stratosphere and a poleward shift and intensification of the SH tropospheric jet is seen under RCP4.5 and RCP8.5, associated with an increase in the SH upper tropospheric meridional temperature gradient (Figure 12.12) (Wilcox et al., 2012). In the NH, the response of the tropospheric jet is weaker and complicated by the additional thermal forcing of polar amplification (Woollings, 2008). Barnes and Polvani (2013) evaluate changes in the annual mean mid-latitude jets in the CMIP5 ensemble, finding consistent poleward shifts in both hemispheres under RCP8.5 for the end of the 21st century. In the NH, the poleward shift is ~1°, similar to that found for the CMIP3 ensemble (Woollings and Blackburn, 2012). In the SH, the annual mean mid-latitude jet shifts poleward by ~2° under RCP8.5 at the end of the 21st century in the CMIP5 multi-model mean (Barnes and Polvani, 2013), with a similar shift of 1.5° in the surface westerlies (Swart and Fyfe, 2012). A strengthening of the SH surface westerlies is also found under all RCPs except RCP2.6 (Swart and Fyfe, 2012), with largest changes in the Pacific basin (Bracegirdle et al., 2013). In austral summer, ozone recovery offsets changes in GHGs to some extent, with a weak reversal of the jet shift found in the multi-model mean under the low emissions scenario of RCP2.6 (Swart and Fyfe, 2012) and weak or poleward shifts in other RCPs (Swart and Fyfe, 2012; Wilcox et al., 2012). Eyring et al. (2013) note the sensitivity of the CMIP5 SH summertime circulation changes to both the strength of the ozone recovery (simulated by some models interactively) and the rate of GHG increases.

Although the poleward shift of the tropospheric jets are robust across models and *likely* under increased GHGs, the dynamical mechanisms behind these projections are still not completely understood and have been explored in both simple and complex models (Chen et al., 2008; Lim and Simmonds, 2009; Butler et al., 2010). The shifts are associated with a strengthening in the upper tropospheric meridional temperature gradient (Wilcox et al., 2012) and hypotheses for associated changes in planetary wave activity and/or synoptic eddy characteristics that impact on the position of the jet have been put forward (Gerber et al., 2012). Equatorward biases in the position of the SH jet (Section 9.5.3.2), while somewhat improved over similar biases in the CMIP3 models (Kidston and Gerber, 2010) still remain, limiting our confidence in the magnitude of future changes.

In summary, poleward shifts in the mid-latitude jets of about 1 to 2 degrees latitude are *likely* at the end of the 21st century under RCP8.5 in both hemispheres (*medium confidence*) with weaker shifts in the NH and under lower emission scenarios. Ozone recovery will *likely* weaken the GHG-induced changes in the SH extratropical circulation in austral summer.

12.4.4.2 Planetary-Scale Overturning Circulations

Large-scale atmospheric overturning circulations and their interaction with other atmospheric mechanisms are significant in determining tropical climate and regional changes in response to enhanced RF. Observed

changes in tropical atmospheric circulation are assessed in Section 2.7.5, while Section 10.3.3 discusses attribution of these observed changes to anthropogenic forcing. Evidence is inconclusive on recent trends in the strength of the Hadley (Stachnik and Schumacher, 2011) and Walker Circulations (Vecchi et al., 2006; Sohn and Park, 2010; Merrifield, 2011; Luo et al., 2012; Tokinaga et al., 2012), though there is *medium confidence* of an anthropogenic influence on the observed widening of the Hadley Circulation (Hu and Fu, 2007; Johanson and Fu, 2009; Davis and Rosenlof, 2012). In the projections, there are indications of a weakening of tropical overturning of air as the climate warms (Held and Soden, 2006; Vecchi and Soden, 2007; Gastineau et al., 2008, 2009; Chou and Chen, 2010; Chadwick et al., 2012; Bony et al., 2013). In the SRES A1B scenario, CMIP3 models show a remarkable agreement in simulating a weakening of the tropical atmospheric overturning circulation (Vecchi and Soden, 2007). CMIP5 models also show a consistent weakening (Chadwick et al., 2012). Along the ascending branches of tropical overturning cells, a reduction in convective mass flux from the boundary layer to the free atmosphere is implied by the differential response to global warming of the boundary-layer moisture content and surface evaporation. This weakening of vertical motion along the ascending regions of both the tropical meridional and near-equatorial zonal cells is associated with an imbalance in the rate of atmospheric moisture increase and that of global mean precipitation (Held and Soden, 2006). A reduction in the compensating climatological subsidence along the downward branches of overturning circulations, where the rate of increase of static stability exceeds radiative cooling, is implied.

Several mechanisms have been suggested for the changes in the intensity of the tropical overturning circulation. The weakening of low-level convective mass flux along ascending regions of tropical overturning cells has been ascribed to changes in the hydrologic cycle (Held and Soden, 2006; Vecchi and Soden, 2007). Advection of dry air from subsidence regions towards the ascending branches of large-scale tropical circulation has been suggested to be a feasible mechanism weakening ascent along the edges of convection regions (Chou et al., 2009). A deepening of the tropical troposphere in response to global warming increases the vertical extent of convection, which has been shown to increase the atmosphere's moist stability and thus also weakening overturning cells (Chou and Chen, 2010). An imbalance between the increase in diabatic heating of the troposphere and in static stability whereby the latter increases more rapidly has also been thought to play a role in weakening tropical ascent (Lu et al., 2008). Mean advection of enhanced vertical stratification under GHG forcing which involves cooling of convective regions and warming of subsidence regions has been shown to slow down tropical cells (Ma et al., 2012). The latest findings using CMIP5 models reveal that an increase in GHGs (particularly CO_2) contributes significantly to weakening tropical overturning cells by reducing radiative cooling in the upper atmosphere (Bony et al., 2013). SST gradients have also been found to play a role in altering the strength of tropical cells (Tokinaga et al., 2012; Ma and Xie, 2013). Evidence has been provided suggesting that the SH Hadley Cell may strengthen in response to meridional SST gradients featuring reduced warming in the SH subtropical oceans relative to the NH, particularly over the Pacific and Indian Oceans (Ma and Xie, 2013). The north-to-south SST warming gradients are a source of intermodel differences in their projections of changes in the SH Hadley Circulation.

Apart from changes in Hadley Circulation strength, a robust feature in 21st century climate model simulations is an increase in the cell's depth and width (Mitas and Clement, 2006; Frierson et al., 2007; Lu et al., 2007; Lu et al., 2008), with the latter change translating to a broadening of tropical regions (Seidel and Randel, 2007; Seidel et al., 2008) and a poleward displacement of subtropical dry zones (Lu et al., 2007; Scheff and Frierson, 2012). The increase in the cell's depth is consistent with a tropical tropopause rise. The projected increase in the height of the tropical tropopause and the associated increase in meridional temperature gradients close to the tropopause slope have been proposed to be an important mechanism behind the Hadley cell expansion and the poleward displacement of the subtropical westerly jet (Lu et al., 2008; Johanson and Fu, 2009). An increase in subtropical and mid-latitude static stability has been found to be an important factor widening the Hadley Cell by shifting baroclinic eddy activity and the associated eddy-driven jet and subsidence poleward (Mitas and Clement, 2006; Lu et al., 2008). The projected widening of the Hadley Cell is consistent with late 20th century observations, where ~2° to 5° latitude expansion was found (Fu et al., 2006; Johanson and Fu, 2009). The consistency of simulated changes in CMIP3 and CMIP5 models and the consistency of Hadley Cell changes with the projected tropopause rise and increase in subtropical and mid-latitude static stability indicate that a widening and weakening of the NH Hadley Cell by the late 21st century is *likely*.

The zonally asymmetric Walker Circulation is projected to weaken under global warming (Power and Kociuba, 2011a, 2011b), more than the Hadley Circulation (Lu et al., 2007; Vecchi and Soden, 2007). The consistency of the projected Walker Circulation slowdown from CMIP3 to CMIP5 suggests that its change is robust (Ma and Xie, 2013). Almost everywhere around the equatorial belt, changes in the 500 hPa vertical motion oppose the climatological background motion, notably over the maritime continent (Vecchi and Soden, 2007; Shongwe et al., 2011). Around the Indo-Pacific warm pool, in response to a spatially uniform SST warming, the climatological upper tropospheric divergence weakens (Ma and Xie, 2013). Changes in the strength of the Walker Circulation also appear to be linked to differential warming between the Indian and Pacific Ocean warming at low latitudes (Luo et al., 2012). Over the equatorial Pacific Ocean, where mid-tropospheric ascent is projected to strengthen, changes in zonal SST and hence sea level pressure gradients induce low-level westerly wind anomalies that act to weaken the low-level branch of the Pacific Walker Circulation. These projected changes in the tropical Pacific circulation are already occurring (Zhang and Song, 2006). However, the projected weakening of the Pacific Walker Cell does not imply an increase in the frequency and/or magnitude of El Niño events (Collins et al., 2010). The consistency of simulated changes in CMIP3 and CMIP5 models and the consistency of Walker Cell changes with equatorial SST and pressure-gradient changes that are already observed indicate that a weakening of the Walker Cell by the late 21st century is *likely*.

In the upper atmosphere, a robust feature of projected stratospheric circulation change is that the Brewer–Dobson circulation will *likely* strengthen in the 21st century (Butchart et al., 2006, 2010; Li et al., 2008; McLandress and Shepherd, 2009; Shepherd and McLandress, 2011). In a majority of model experiments, the projected changes in the large-scale overturning circulation in the stratosphere feature an

intensification of tropical upward mass flux, which may extend to the upper stratosphere. The proposed driver of the increase in mass flux at the tropical lower stratosphere is the enhanced propagation of wave activity, mainly resolved planetary waves, associated with a positive trend in zonal wind structure (Butchart and Scaife, 2001; Garcia and Randel, 2008). In the 21st century, increases in wave excitation from diabatic heating in the upper tropical troposphere could reinforce the wave forcing on the tropical upwelling branch of the stratospheric mean meridional circulation (Calvo and Garcia, 2009). Parameterized orographic gravity waves that result from strengthening of subtropical westerly jets and cause more waves to propagate into the lower stratosphere also play a role (Sigmond et al., 2004; Butchart et al., 2006). The projected intensification in tropical upwelling is counteracted by enhanced mean extratropical/polar lower stratospheric subsidence. In the NH high latitudes, the enhanced downwelling is associated with an increase in stationary planetary wave activities (McLandress and Shepherd, 2009). The intensification of the stratospheric meridional residual circulation has already been reported in studies focussing on the last decades of the 20th century (Garcia and Randel, 2008; Li et al., 2008; Young et al., 2012). The projected increase in troposphere-to-stratosphere mass exchange rate (Butchart et al., 2006) and stratospheric mixing associated with the strengthening of the Brewer–Dobson circulation will *likely* result in a decrease in the mean age of air in the lower stratosphere. In the mid-latitude lower stratosphere, quasi-horizontal mixing is a significant contributor to reducing the lifetimes of air. There are some suggestions that the changes in stratospheric overturning circulation could lead to a reduction in tropical ozone concentrations and an increase at high latitudes (Jiang et al., 2007) and an increase in the amplitude of the annual cycle of stratospheric ozone (Randel et al., 2007).

12.4.4.3 Extratropical Storms: Tracks and Influences on Planetary-Scale Circulation and Transports

Since the AR4, there has been continued evaluation of changes in extratropical storm tracks under projected warming using both CMIP3 and, more recently, CMIP5 simulations, as well as supporting studies using single models or idealized simulations. CMIP3 analyses use a variety of methods for diagnosing storm tracks, but diagnosis of changes in the tracks appears to be relatively insensitive to methods used (Ulbrich et al., 2013). Analyses of SH storm tracks generally agree with earlier studies, showing that extratropical storm tracks will tend to shift poleward (Bengtsson et al., 2009; Gastineau et al., 2009; Gastineau and Soden, 2009; Perrie et al., 2010; Schuenemann and Cassano, 2010; Chang et al., 2012b). The behaviour is consistent with a *likely* trend in observed storm-track behaviour (see Section 2.7.6). Similar behaviour appears in CMIP5 simulations for the SH (Figure 12.20c, d). In SH winter there is a clear poleward shift in storm tracks of several degrees and a reduction in storm frequency of only a few percent (not shown). The poleward shift at the end of the century is consistent with a poleward shift in the SH of the latitudes with strongest tropospheric jets (Figure 12.19). This appears to coincide with shifts in baroclinic dynamics governing extratropical storms (Frederiksen et al., 2011), though the degree of jet shift appears to be sensitive to bias in a model's contemporary-climate storm tracks (Chang et al., 2012a, 2012b). Although there is thus some uncertainty in the degree of shift, the consistency of behaviour with observation-based trends, consistency between CMIP5 and CMIP3 projections under a variety of diagnostics and the physical consistency of the storm response with other climatic changes gives *high confidence* that a poleward shift of several degrees in SH storm tracks is *likely* by the end of the 21st century under the RCP8.5 scenario.

In the NH winter (Figure 12.20a, b), the CMIP5 multi-model ensemble shows an overall reduced frequency of storms and less indication of a poleward shift in the tracks. The clearest poleward shift in the NH winter at the end of the 21st century occurs in the Asia-Pacific storm track, where intensification of the westerly jet promotes more intense cyclones in an ensemble of CMIP5 models (Mizuta, 2012). Otherwise, changes in winter storm-track magnitude, as measured by band-pass sea level pressure fluctuations, show only small change relative to interannual and inter-decadal variability by the end of the 21st century in SRES A1B and RCP4.5 simulations for several land areas over the NH (Harvey et al., 2012). Consistency in CMIP3 and CMIP5 changes seen in the SH are absent in the NH (Chang et al., 2012a). Factors identified that affect changes in the North Atlantic basin's storm track include horizontal resolution (Colle et al., 2013) and how models simulate changes in the Atlantic's meridional overturning circulation (Catto et al., 2011; Woollings et al., 2012), the zonal jet and Hadley Circulation (Mizuta, 2012; Zappa et al., 2013) and subtropical upper troposphere temperature (Haarsma et al., 2013). Substantial uncertainty and thus *low confidence* remains in projecting changes in NH winter storm tracks, especially for the North Atlantic basin.

Additional analyses of CMIP3 GCMs have determined other changes in properties of extratropical storms. Most analyses find that the frequency of storms decreases in projected climates (Finnis et al., 2007; Favre and Gershunov, 2009; Dowdy et al., 2013), though the occurrence of strong storms may increase in some regions (Pinto et al., 2007; Bengtsson et al., 2009; Ulbrich et al., 2009; Zappa et al., 2013). Many studies focus on behaviour of specific regions, and results of these studies are detailed in Section 14.6.2.

Changes in extratropical storms in turn may influence other large-scale climatic changes. Kug et al. (2010) in a set of time-slice simulations show that a poleward shift of storm tracks in the NH could enhance polar warming and moistening. The Arctic Oscillation (AO) is sensitive to synoptic eddy vorticity flux, so that projected changes in storm tracks can alter the AO (Choi et al., 2010). The net result is that changes in extratropical storms alter the climate in which they are embedded, so that links between surface warming, extratropical storms and their influence on climate are more complex than simple responses to changes in baroclinicity (O'Gorman, 2010).

12.4.5 Changes in the Water Cycle

The water cycle consists of water stored on the Earth in all its phases, along with the movement of water through the Earth's climate system. In the atmosphere, water occurs primarily as gaseous water vapour, but it also occurs as solid ice and liquid water in clouds. The ocean is primarily liquid water, but is partly covered by ice in polar regions. Terrestrial water in liquid form appears as surface water (lakes, rivers), soil moisture and groundwater. Solid terrestrial water occurs in ice sheets, glaciers, frozen lakes, snow and ice on the surface and permafrost.

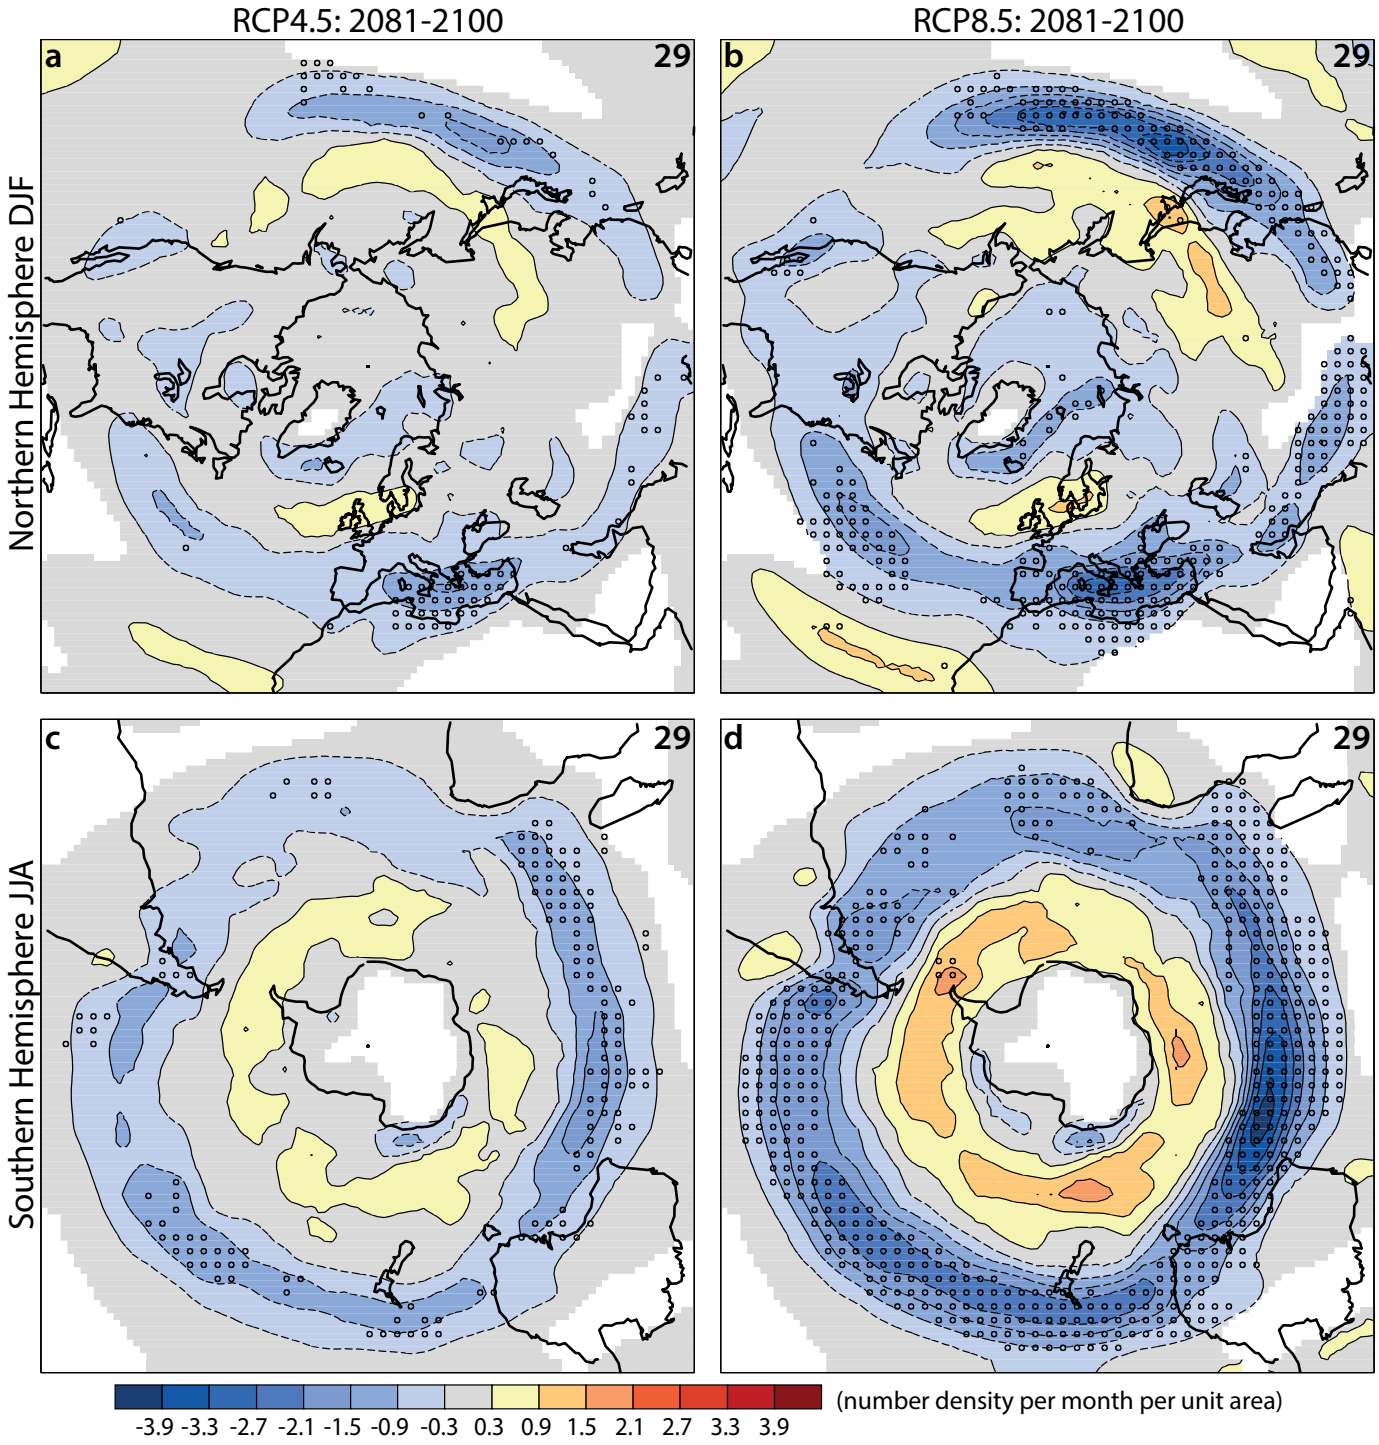

Figure 12.20 | Change in winter, extratropical storm track density (2081–2100) – (1986–2005) in CMIP5 multi-model ensembles: (a) RCP4.5 Northern Hemisphere December, January and February (DJF) and (b) RCP8.5 Northern Hemisphere DJF, (c) RCP4.5 Southern Hemisphere June, July and August (JJA) and (d) RCP8.5 Southern Hemisphere JJA. Storm-track computation uses the method of Bengtsson et al. (2006, their Figure 13a) applied to 6-hourly 850 hPa vorticity computed from horizontal winds in the CMIP5 archive. The number of models used appears in the upper right of each panel. DJF panels include data for December 1985 and 2080 and exclude December 2005 and December 2100 for in-season continuity. Stippling marks locations where at least 90% of the models agree on the sign of the change; note that this criterion differs from that used for many other figures in this chapter, due to the small number of models providing sufficient data to estimate internal variability of 20-year means of storm-track statistics. Densities have units (number density per month per unit area), where the unit area is equivalent to a 5° spherical cap (~10^6 km^2). Locations where the scenario or contemporary-climate ensemble average is below 0.5 density units are left white.

Projections of future changes in the water cycle are inextricably connected to changes in the energy cycle (Section 12.4.3) and atmospheric circulation (Section 12.4.4).

Saturation vapour pressure increases with temperature, but projected future changes in the water cycle are far more complex than projected temperature changes. Some regions of the world will be subject to decreases in hydrologic activity while others will be subject to increases. There are important local seasonal differences among the responses of the water cycle to climate change as well.

At first sight, the water cycles simulated by CMIP3/5 models may appear to be inconsistent, particularly at regional scales. Anthropogenic changes to the water cycle are superimposed on complex naturally varying modes of the climate (such as El Niño-Southern Oscillation (ENSO), AO, Pacific Decadal Oscillation (PDO), etc.) aggravating the differences between model projections. However, by careful consideration of the interaction of the water cycle with changes in other aspects of the climate system, the mechanisms of change are revealed, increasing confidence in projections.

12.4.5.1 Atmospheric Humidity

Atmospheric water vapour is the primary GHG in the atmosphere. Its changes affect all parts of the water cycle. However, the amount of water vapour is dominated by naturally occurring processes and not significantly affected directly by human activities. A common experience from past modelling studies is that relative humidity (RH) remains approximately constant on climatological time scales and planetary space scales, implying a strong constraint by the Clausius–Clapeyron relationship on how specific humidity will change. The AR4 stated that 'a broad-scale, quasi-unchanged RH response [to climate change] is uncontroversial' (Randall et al., 2007). However, underlying this fairly straightforward behaviour are changes in RH that can influence changes in cloud cover and atmospheric convection (Sherwood, 2010). More recent analysis provides further detail and insight on RH changes. Analysis of CMIP3 and CMIP5 models shows near-surface RH decreasing over most land areas as temperatures increase with the notable exception of parts of tropical Africa (O'Gorman and Muller, 2010) (Figure 12.21). The prime contributor to these decreases in RH over land is the larger temperature increases over land than over ocean in the RCP scenarios (Joshi et al., 2008; Fasullo, 2010; O'Gorman and Muller, 2010). The specific humidity of air originating over more slowly warming oceans will be governed by saturation temperatures of oceanic air. As this air moves over land and is warmed, its relative humidity drops as any further moistening of the air over land is insufficient to maintain constant RH, a behaviour Sherwood et al. (2010) term a last-saturation-temperature constraint. The RH decrease over most land areas by the end of the 21st century is consistent with a last-saturation-temperature constraint and with observed behaviour during the first decade of the current century (Section 2.5.5; Simmons et al., 2010). Land–ocean differences in warming are projected to continue through the 21st century, and although the CMIP5 projected changes are small, they are consistent with a last-saturation constraint, indicating with *medium confidence* that reductions in near-surface RH over many land areas are *likely*.

12.4.5.2 Patterns of Projected Average Precipitation Changes

Global mean precipitation changes have been presented in Section 12.4.1.1. The processes that govern large-scale changes in precipitation are presented in Section 7.6, and are used here to interpret the

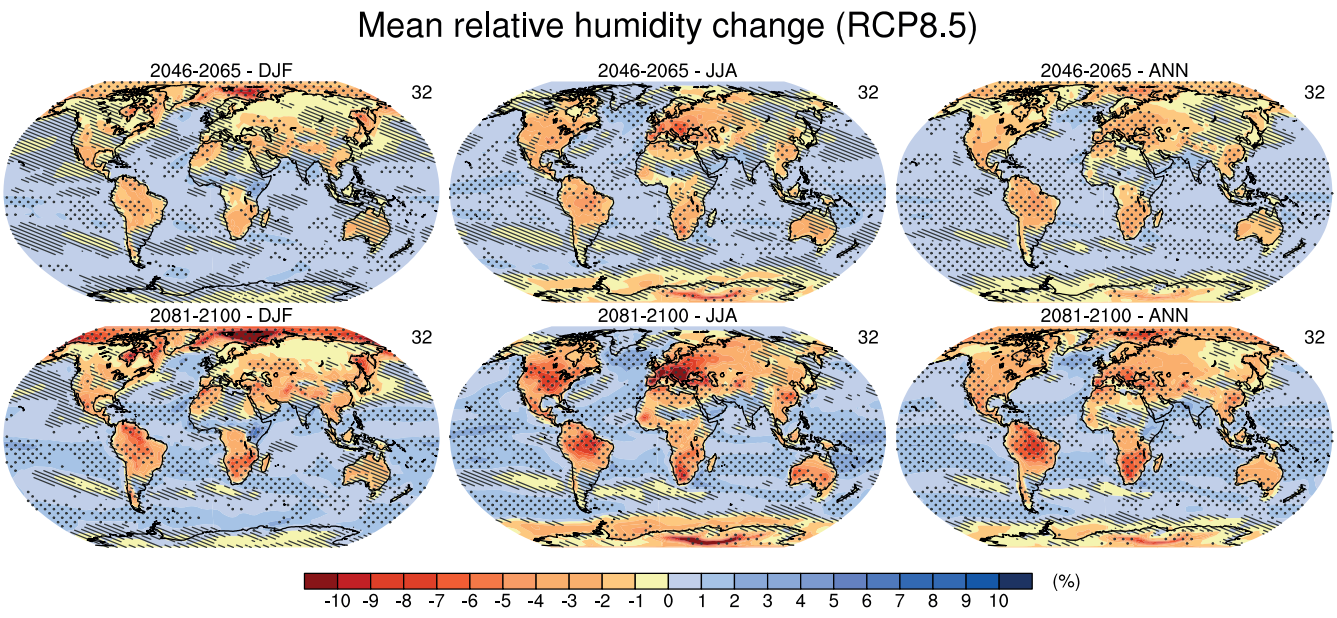

Figure 12.21 | Projected changes in near-surface relative humidity from the CMIP5 models under RCP8.5 for the December, January and February (DJF, left), June, July and August (JJA, middle) and annual mean (ANN, right) averages relative to 1986–2005 for the periods 2046–2065 (top row), 2081–2100 (bottom row). The changes are differences in relative humidity percentage (as opposed to a fractional or relative change). Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of models agree on the sign of change (see Box 12.1).

projected changes in RCP scenarios. Changes in precipitation extremes are presented in Section 12.4.5.5. Further discussion of regional changes, in particular the monsoon systems, is presented in Chapter 14.

Figure 12.22 shows the CMIP5 multi-model average percentage change in seasonal mean precipitation in the middle of the 21st century, at the end of the 21st century and at the end of the 22nd century for the RCP8.5 scenario relative to the 1986–2005 average. Precipitation changes for all the scenarios are shown in Annex I Supplementary Material and scale approximately with the global mean temperature (Section 12.4.2). In many regions, changes in precipitation exhibit strong seasonal characteristics so that, in regions where the sign of the precipitation changes varies with the season, the annual mean values (Figure 12.10) may hide some of these seasonal changes, resulting in weaker confidence than seasonal mean values (Chou et al., 2013; Huang et al., 2013).

The patterns of multi-model precipitation changes displayed in Figure 12.22 tend to smooth and decrease the spatial contrast of precipitation changes simulated by each model, in particular over regions where model results disagree. Thus the amplitude of the multi-model ensemble mean precipitation response significantly underestimates the median amplitude computed from each individual model (Neelin et al., 2006; Knutti et al., 2010a). The CMIP3/5 multi-model ensemble precipitation projections must be interpreted in the context of uncertainty. Multi-model projections are not probabilistic statements about the likelihood of changes. Maps of multi-model projected changes are smoothly varying but observed changes are and will continue to be much more granular.

To analyze the patterns of projected precipitation changes, a useful framework consists in decomposing them into a part that is related to atmospheric circulation changes and a part that is related mostly to water vapour changes, referred to as dynamical and thermodynamical components, respectively. However, the definition of these two components may differ among studies. At the time of the AR4, the robust changes of the difference between precipitation and evaporation ($P - E$) were interpreted as a wet-get-wetter and dry-get-drier type of response (Mitchell et al., 1987; Chou and Neelin, 2004; Held and Soden, 2006). The theoretical background, which is more relevant over oceans than over land, is that the lower-tropospheric water vapour increase with temperature enhances the moisture transported by the circulation. This leads to additional moisture convergence within the convergence zones and to additional moisture divergence in the descent zones, increasing the contrast in precipitation minus evaporation values between moisture convergence and divergence regions. A weakening of the tropical overturning circulation (see Section 12.4.4.2) partially opposes this thermodynamic response (Chou and Neelin, 2004; Held and Soden, 2006; Vecchi and Soden, 2007; Chou et al., 2009; Seager et al., 2010; Allan, 2012; Bony et al., 2013). At the regional scale the dynamic response may be larger than the thermodynamic response, and this has been analyzed in more detail since the AR4 (Chou et al., 2009; Seager et al., 2010; Xie et al., 2010; Muller and O'Gorman, 2011; Chadwick et al., 2012; Scheff and Frierson, 2012; Bony et al., 2013; Ma and Xie, 2013). Over continents, this simple wet-get-wetter and dry-get-drier type of response fails for some important regions such as the Amazon. At the global scale, the net water vapour transport from oceans to land increases, and therefore the average $P - E$ over continents also increases (Liepert and Previdi, 2012).

In the mid and high latitudes, a common feature across generations of climate models is a simulated increased precipitation. The thermodynamical component explains most of the projected increase (Emori and Brown, 2005; Seager et al., 2010). This is consistent with theoretical explanations assuming fixed atmospheric flow patterns but increased water vapour in the lower troposphere (Held and Soden, 2006). In addition to this thermodynamical effect, water transport may be modified by the poleward shift of the storm tracks and by the increase of their intensity (Seager et al., 2010; Wu et al., 2011b), although confidence in such changes in storm tracks may not be high (see Section 12.4.4). On seasonal time scales, the minimum and maximum values of precipitation both increase, with a larger increase of the maximum and therefore an increase of the annual precipitation range (Seager et al., 2010; Chou and Lan, 2012). In particular, the largest changes over northern Eurasia and North America are projected to occur during winter. At high latitudes of the NH, the precipitation increase may lead to an increase of snowfall in the colder regions and a decrease of snowfall in the warmer regions due to the decreased number of freezing days (see Section 12.4.6.2).

Most models simulate a large increase of the annual mean precipitation over the equatorial ocean and an equatorward shift of the Intertropical Convergence Zone (ITCZ), in both summer and winter seasons, that are mainly explained by atmospheric circulation changes (Chou et al., 2009; Seager et al., 2010; Sobel and Camargo, 2011). The changes of the atmospheric circulation have different origins. Along the margins of the convection zones, spatial inhomogeneities, including local convergence feedback or the rate at which air masses from dry regions tend to flow into the convection zone, can yield a considerable sensitivity in precipitation response (Chou et al., 2006; Neelin et al., 2006). Along the equator, atmosphere–ocean interactions yield to a maximum of SST warming and a large precipitation increase there (Xie et al., 2010; Ma and Xie, 2013). Model studies with idealized configurations suggest that tropical precipitation changes should be interpreted as responses to changes of the atmospheric energy budget rather than responses to changes of SST (Kang and Held, 2012). All of these atmospheric circulation changes, and therefore precipitation changes, can differ considerably from model to model. This is the case over both ocean and land. For instance, the spread of model projections in the Sahel region, West Africa, is large in both the CMIP3 and CMIP5 multi-model data base (Roehrig et al., 2013).

In the subtropical dry regions, there is a robust decrease of $P - E$ that is accounted for by the thermodynamic contribution (Chou and Neelin, 2004; Held and Soden, 2006; Chou et al., 2009; Seager et al., 2010; Bony et al., 2013). Over ocean, the spatial heterogeneity of temperature increase impacts the lower-tropospheric water vapour increase, which impacts both the thermodynamic and the dynamic responses (Xie et al., 2010; Ma and Xie, 2013). In addition, the pattern of precipitation changes in dry regions may be different from that of $P - E$ because the contribution of evaporation changes can be as large (but of opposite sign) as the moisture transport changes (Chou and Lan, 2012; Scheff and Frierson, 2012; Bony et al., 2013). This is especially the case over the subsidence regions during the warm season over land where the

agreement between models is the smallest (Chou et al., 2009; Allan, 2012). A robust feature is the decline of precipitation on the poleward flanks of the subtropical dry zones as a consequence of the Hadley Cell expansion, with possible additional decrease from a poleward shift of the mid latitude storm tracks (Seager et al., 2010; Scheff and Frierson, 2012). On seasonal time scales, the minimum and the maximum values of precipitation both increase, with a larger increase of the maximum and therefore an increase of the annual precipitation range (Sobel and Camargo, 2011; Chou and Lan, 2012).

Long-term precipitation changes are driven mainly by the increase of the surface temperature, as presented above, but other factors also contribute to them. Recent studies suggest that CO_2 increase has a significant direct influence on atmospheric circulation, and therefore on global and tropical precipitation changes (Andrews et al., 2010; Bala et al., 2010; Cao et al., 2012; Bony et al., 2013). Over the ocean, the positive RF from increased atmospheric CO_2 reduces the radiative cooling of the troposphere and the large scale rising motion and hence reduces precipitation in the convective regions. Over large landmasses, the direct effect of CO_2 on precipitation is the opposite owing to the small thermal inertia of land surfaces (Andrews et al., 2010; Bala et al., 2010; Cao et al., 2012; Bony et al., 2013). Regional precipitation changes are also influenced by aerosol and ozone (Ramanathan et al., 2001; Allen et al., 2012; Shindell et al., 2013a) through both local and large-scale processes, including changes in the circulation. Stratospheric ozone depletion contributes to the poleward expansion of the Hadley Cell and the related change of precipitation in the SH (Kang et al., 2011) whereas black carbon and tropospheric ozone increases are major contributors in the NH (Allen et al., 2012). Regional precipitation changes depend on regional forcings and on how models simulate their local and remote effects. Based on CMIP3 results, the inter-model spread of the estimate of precipitation changes over land is larger than the inter-scenario spread except in East Asia (Frieler et al., 2012).

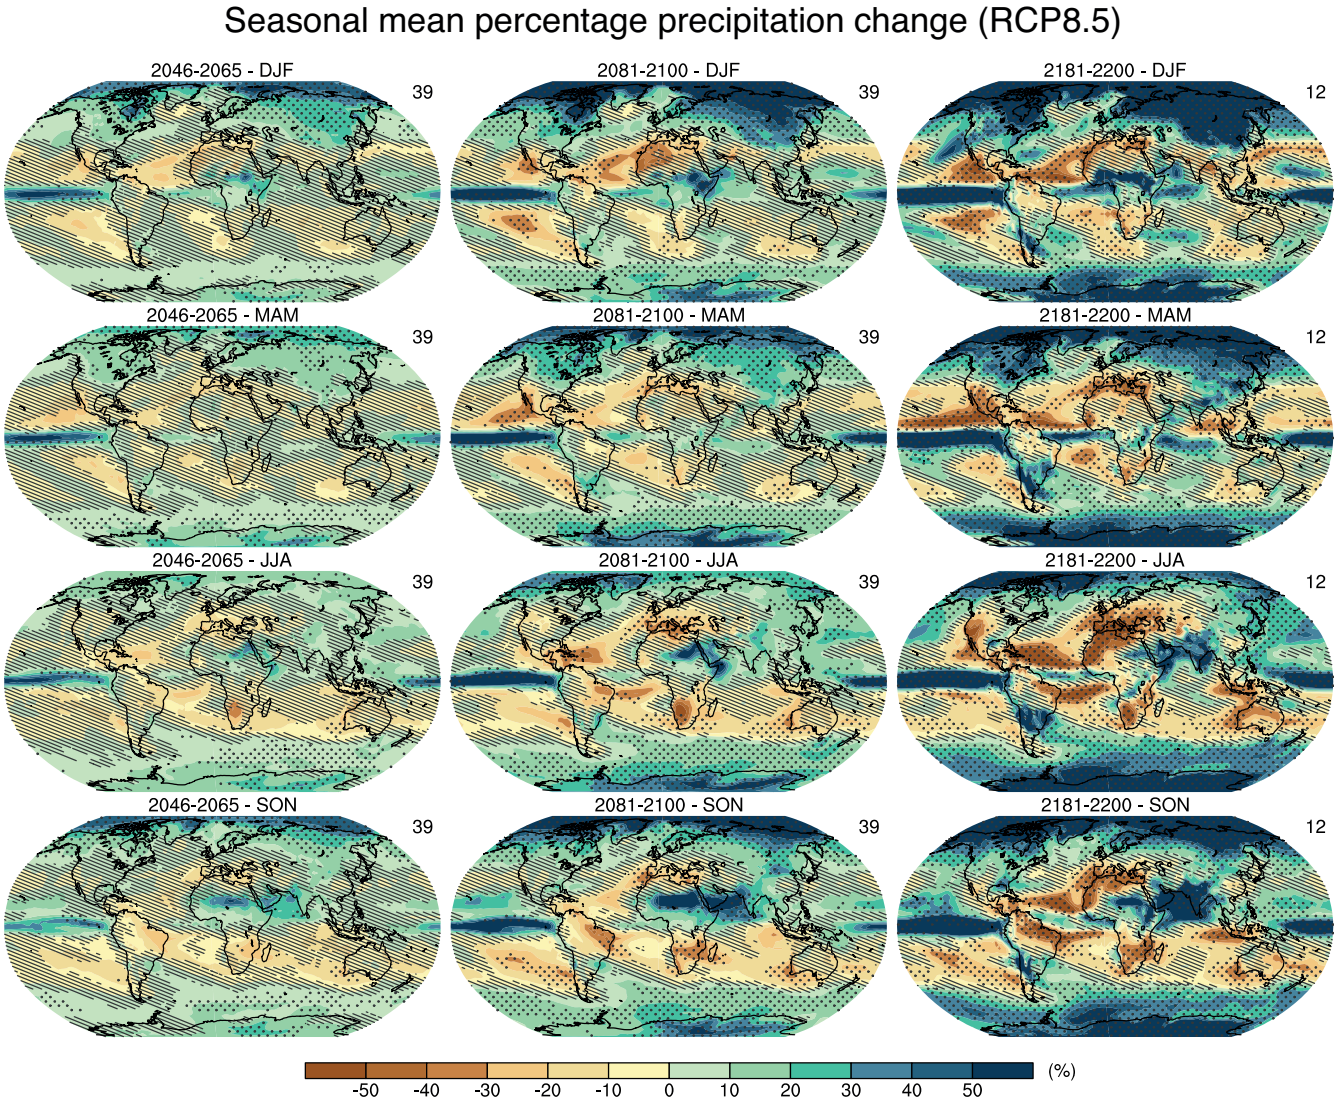

Figure 12.22 | Multi-model CMIP5 average percentage change in seasonal mean precipitation relative to the reference period 1986–2005 averaged over the periods 2045–2065, 2081–2100 and 2181–2200 under the RCP8.5 forcing scenario. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of models agree on the sign of change (see Box 12.1).

Projected precipitation changes vary greatly between models, much more so than for temperature projections. Part of this variance is due to genuine differences between the models including their ability to replicate observed precipitation patterns (see Section 9.4.1.1). However, a large part of it is also the result of the small ensemble size from each model (Rowell, 2012). This is especially true for regions of small projected changes located between two regions: one experiencing significant increases while the other experiences significant decreases. Individual climate model realizations will differ in their projection of future precipitation changes in these regions simply owing to their internal variability (Deser et al., 2012b; Deser et al., 2012a). Multi-model projections containing large numbers of realizations would tend to feature small changes in these regions, and hatching in Figure 12.22 indicates regions where the projected multi-model mean change is less than one standard deviation of internal variability (method (a), Box 12.1). Confidence in projections in regions of limited or no change in precipitation may be more difficult to obtain than confidence in regions of large projected changes. However, Power et al. (2012) and Tebaldi et al. (2011) show that for some of the regions featuring small multi-model average projected changes, effective consensus in projections may be better than the metrics reported in AR4 would imply.

Since the AR4, progress has been made in the understanding of the processes that control large scale precipitation changes. There is *high confidence* that the contrast of seasonal mean precipitation between dry and wet regions will increase in a warmer climate over most of the globe although there may be regional exceptions to this general pattern. This response is particularly robust when considering $P - E$ changes as a function of atmospheric dynamical regimes. However, it is important to note that significant exceptions can occur in specific regions especially along the equator and on the poleward edges of the subtropical dry zone. In these regions, atmospheric circulation changes lead to shifts of the precipitation patterns. There is *high confidence* that the contrast between wet and dry seasons will increase over most of the globe as temperatures increase. Over the mid- and high-latitude regions, projected precipitation increases in winter are larger than in summer. Over most of the subtropical oceans, projected precipitation increases in summer are larger than in winter.

The changes in precipitation shown in Figure 12.22 exhibit patterns that become more pronounced and confidence in them increases as temperatures increase. More generally, the spatial and temporal changes in precipitation between two scenarios or within two periods of a given scenario exhibit the pattern scaling behavior and limitations described in Section 12.4.2. The patterns and the associated multi-model spreads in CMIP5 for the RCP scenarios are very similar to those in CMIP3 for the SRES scenarios discussed in the AR4, with the projections in CMIP5 being slightly more consistent over land than those from CMIP3 (Knutti and Sedláček, 2013). The largest percentage changes are at the high latitudes. By the end of the 21st century, over the large northern land masses, increased precipitation is *likely* under the RCP8.5 scenario in the winter and spring poleward of 50°N. The robustness across scenarios, the magnitude of the projected changes versus natural variability and physical explanations described above yield *high confidence* that the projected changes would be larger than natural 20-year variations (see Box 12.1). In the tropics, precipitation changes exhibit strong regional contrasts, with increased precipitation over the equatorial Pacific and Indian Oceans and decreases over much of the subtropical ocean. However, decreases are not projected to be larger than natural 20-year variations anywhere until the end of this century under the RCP8.5 scenario. Decreased precipitation in the Mediterranean, Caribbean and Central America, southwestern United States and South Africa is *likely* under the RCP8.5 scenario and is projected with *medium confidence* to be larger than natural variations by the end of the 22nd century in some seasons (Box 12.1). The CMIP3 models' historical simulations of zonal mean precipitation trends were shown to underestimate observed trends (Gillett et al., 2004; Lambert et al., 2005; Zhang et al., 2007; Liepert and Previdi, 2009) (see Section 10.3.2.2). Therefore it is *more likely than not* that the magnitude of the projected future changes in Figure 12.22 based on the multi-model mean is underestimated. Observational uncertainties including limited global coverage and large natural variability, in addition to challenges in precipitation modelling, limit confidence in assessment of climatic changes in precipitation.

12.4.5.3 Soil Moisture

Near-surface soil moisture is the net result of a suite of complex processes (e.g., precipitation evapotranspiration, drainage, overland flow, infiltration), and heterogeneous and difficult-to-characterize aboveground and belowground system properties (e.g., slope, soil texture). As a result, regional to global-scale simulations of soil moisture and drought remain relatively uncertain (Burke and Brown, 2008; Henderson-Sellers et al., 2008). The AR4 (Section 8.2.3.2) discussed the lack of assessments of global-scale models in their ability to simulate soil moisture, and this problem appears to have persisted (Section 9.4.4.2). Furthermore, consistent multi-model projections of total soil moisture are difficult to make owing to substantial differences between climate models in the depth of their soil. However, Koster et al. (2009a) argued that once climatological statistics affecting soil moisture were accounted for, different models tend to agree on soil moisture projections.

The AR4 summarized multi-model projections of 21st century annual mean soil moisture changes as decreasing in the subtropics and Mediterranean region, and increasing in east Africa and central Asia. Dai (2013) found similar changes in an ensemble of 11 CMIP5 GCMs under RCP4.5. Figure 12.23 shows projected changes in surface soil moisture (upper 10 cm) in the CMIP5 ensemble at the end of the 21st century under the RCPs 2.6, 4.5, 6.0 and 8.5. We focus on this new CMIP5 specification because it describes soil moisture at a consistent depth across all CMIP5 models. The broad patterns are moderately consistent across the RCPs, with the changes tending to become stronger as the strength of the forcing change increases. The agreement among CMIP5 models and the consistency with other physical features of climate change indicate *high confidence* in certain regions where surface soils are projected to dry. There is little-to-no confidence anywhere in projections of moister surface soils. Under RCP8.5, with the largest projected change, individual ensemble members (not shown) show consistency across the ensemble for drying in the Mediterranean region, northeast and southwest South America, southern Africa, and southwestern USA. However, ensemble members show disagreement on the sign of change in large regions such as central Asia or the high northern latitudes. The Mediterranean, southwestern USA, northeast South America and southern African drying regions are consistent with

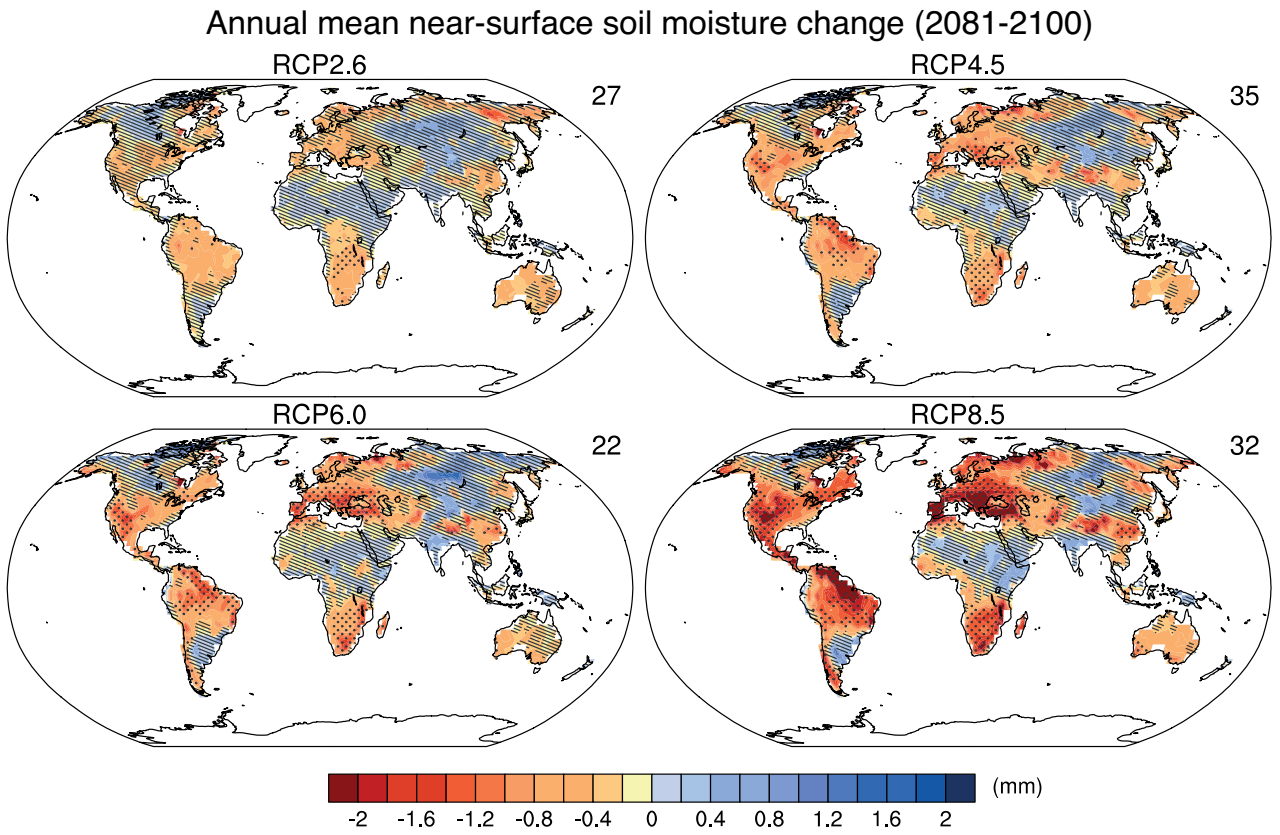

Figure 12.23 | Change in annual mean soil moisture (mass of water in all phases in the uppermost 10 cm of the soil) (mm) relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

projected widening of the Hadley Circulation that shifts downwelling, thus inhibiting precipitation in these regions. The large-scale drying in the Mediterranean, southwest USA, and southern Africa appear across generations of projections and climate models and is deemed *likely* as global temperatures rise and will increase the risk of agricultural drought. In addition, an analysis of CMIP3 and CMIP5 projections of soil moisture in five drought-prone regions indicates that the differences in future forcing scenarios are the largest source of uncertainty in such regions rather than differences between model responses (Orlowsky and Seneviratne, 2012).

Other recent assessments include multi-model ensemble approaches, dynamical downscaling, and regional climate models applied around the globe and illustrate the variety of issues influencing soil moisture changes. Analyses of the southwestern USA using CMIP3 models (Christensen and Lettenmaier, 2007; Seager et al., 2007) show consistent projections of drying, primarily due to a decrease in winter precipitation. In contrast, Kellomaki et al. (2010) find that SRES A2 projections for Finland yield decreased snow depth, but soil moisture generally increases, consistent with the general increase in precipitation occurring in high northern latitudes. Kolomyts and Surova (2010), using projections from the CMIP3 models, GISS and HadCM2, under the SRES A2 forcing, show that vegetation type has substantial influence on the development of pronounced drying over the 21st century in Middle Volga Region forests.

Projected changes in soil moisture from the CMIP3/5 models also show substantial seasonal variation. For example, soil moisture changes in the North American midlatitudes, coupled with projected warming, increases the strength of land–atmosphere coupling during spring and summer in 15 GCMs under RCP8.5 (Dirmeyer et al., 2013). For the Cline River watershed in western Canada, Kienzle et al. (2012) find decreases in summer soil moisture content, but annual increases averaging 2.6% by the 2080s using a suite of CMIP3 GCMs simulating B1, A1B and A2 scenarios to drive a regional hydrology model. Hansen et al. (2007), using dynamical downscaling of one GCM running the A2 scenario, find summer soil moisture decreases in Mongolia of up to 6% due to increased potential evaporation in a warming climate and decreased precipitation and decreased precipitation.

Soil moisture projections in high latitude permafrost regions are critically important for assessing future climate feedbacks from trace-gas emissions (Zhuang et al., 2004; Riley et al., 2011) and vegetation changes (Chapin et al., 2005). In addition to changes in precipitation, snow cover and evapotranspiration, future changes in high-latitude soil moisture also will depend on permafrost degradation, thermokarst evolution, rapid changes in drainage (Smith et al., 2005), and changes in plant communities and their water demands. Current understanding of these interacting processes at scales relevant to climate is poor, so that full incorporation in current GCMs is lacking.

12.4.5.4 Runoff and Evaporation

In the AR4, 21st century model-projected runoff consistently showed decreases in southern Europe, the Middle East, and southwestern USA and increases in Southeast Asia, tropical East Africa and at high northern latitudes. The same general features appear in the CMIP5 ensemble of GCMs for all four RCPs shown in Figure 12.24, with the areas of most robust change typically increasing with magnitude of forcing change. However, the robustness of runoff decreases in the southwestern USA is less in the CMIP5 models compared to the AR4. The large decreases in runoff in southern Europe and southern Africa are consistent with changes in the Hadley Circulation and related precipitation decreases and warming-induced evapotranspiration increases. The high northern latitude runoff increases are *likely* under RCP8.5 and consistent with the projected precipitation increases (Figure 12.22). The consistency of changes across different generations of models and different forcing scenarios, together with the physical consistency of change indicates that decreases are also *likely* in runoff in southern Europe, the Middle East, and southern Africa in this scenario.

A number of reports since the AR4 have updated findings from CMIP3 models and analyzed a large set of mechanisms affecting runoff. Several studies have focussed on the Colorado River basin in the United States (Christensen and Lettenmaier, 2007; McCabe and Wolock, 2007; Barnett and Pierce, 2008; Barnett et al., 2008) showing that runoff reductions that do happen under global warming occur through a combination of evapotranspiration increases and precipitation decreases, with the overall reduction in river flow exacerbated by human water demands on the basin's supply.

A number of CMIP3 analyses have examined trends and seasonal shifts in runoff. For example, Kienzle et al. (2012) studied climate change scenarios over the Cline River watershed in western Canada and projected (1) spring runoff and peak streamflow up to 4 weeks earlier than in 1961–1990; (2) significantly higher streamflow between October and June; and (3) lower streamflow between July and September. For the Mediterranean basin, an ensemble of regional climate models driven by several GCMs using the A1B scenario have a robust decrease in runoff emerging only after 2050 (Sanchez-Gomez et al., 2009).

Annual mean surface evaporation in the models assessed in AR4 showed increases over most of the ocean and increases or decreases over land with largely the same pattern over land as increases and decreases in precipitation. Similar behaviour occurs in an ensemble of CMIP5 models (Figure 12.25). Evaporation increases over most of the ocean and land, with prominent areas of decrease over land occurring in southern Africa and northwestern Africa along the Mediterranean. The areas of decrease correspond to areas with reduced precipitation. There is some uncertainty about storm-track changes over Europe (see Sections 12.4.3 and 14.6.2). However, the consistency of the decreases across different generations of models and different forcing scenarios along with the physical basis for the precipitation decrease

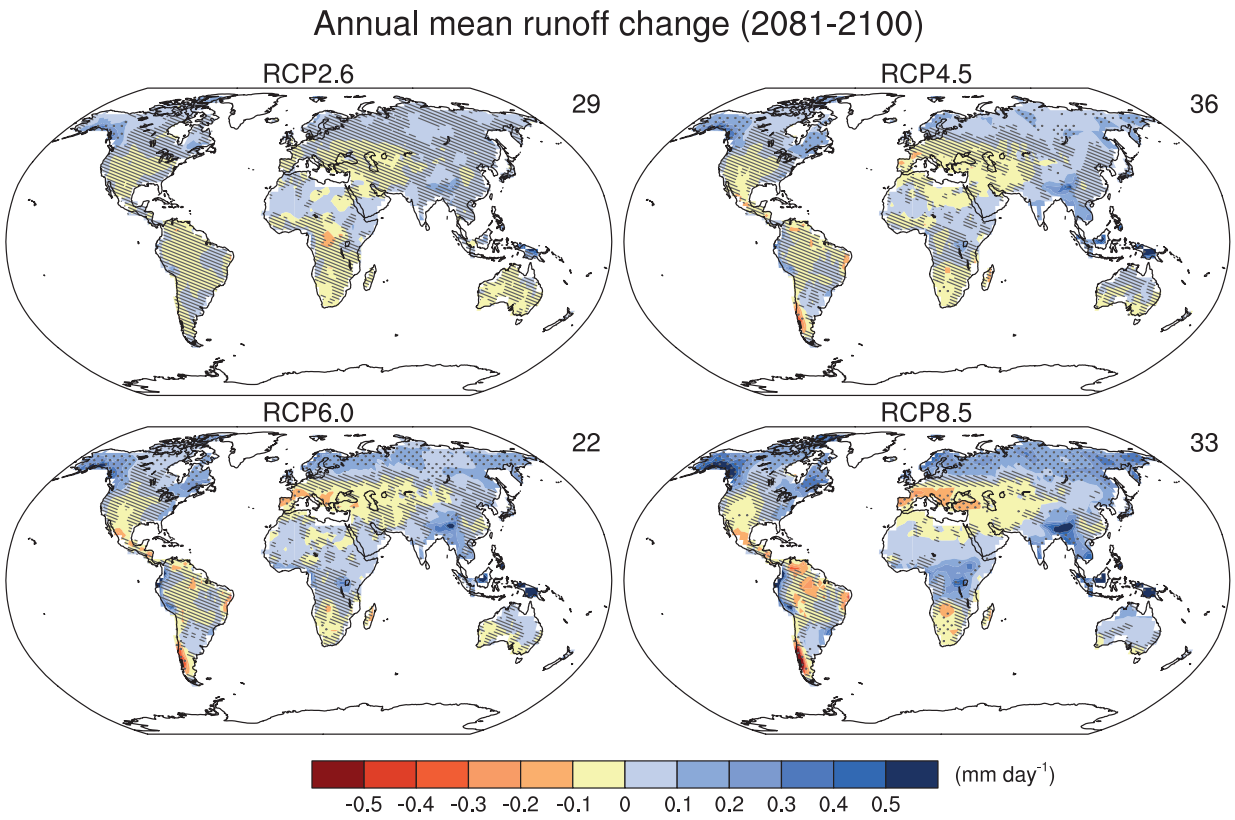

Figure 12.24 | Change in annual mean runoff relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

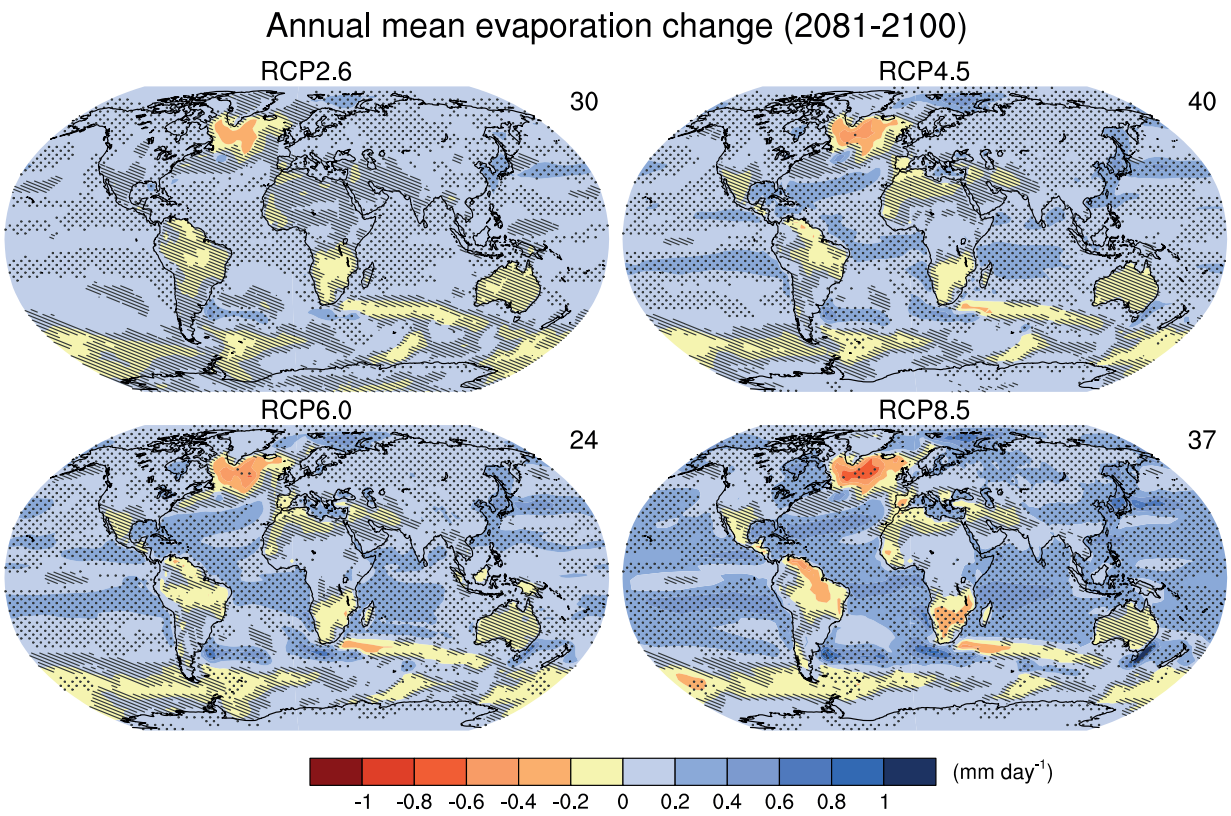

Figure 12.25 | Change in annual mean evaporation relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

indicates that these decreases in annual mean evaporation are *likely* under RCP8.5, but with *medium confidence.* Annual mean evaporation increases over land in the northern high latitudes are consistent with the increase in precipitation and the overall warming that would increase potential evaporation. For the northern high latitudes, the physical consistency and the similar behaviour across multiple generations and forcing scenarios indicates that annual mean evaporation increases there are *likely*, with *high confidence*.

Evapotranspiration changes partly reflect changes in precipitation. However, some changes might come from altered biological processes. For example, increased atmospheric CO_2 promotes stomatal closure and reduced transpiration (Betts et al., 2007; Cruz et al., 2010) which can potentially yield increased runoff. There is potential for substantial feedback between vegetation changes and regional water cycles, though the impact of such feedback remains uncertain at this point due to limitations on modelling crop and other vegetation processes in GCMs (e.g., Newlands et al., 2012) and uncertainties in plant response, ecosystem shifts and land management changes.

12.4.5.5 Extreme Events in the Water Cycle

In addition to the changes in the seasonal pattern of mean precipitation described above, the distribution of precipitation events is projected to undergo profound changes (Gutowski et al., 2007; Sun et al., 2007; Boberg et al., 2010). At daily to weekly scales, a shift to more intense individual storms and fewer weak storms is projected (Seneviratne et al., 2012). At seasonal or longer time scales, increased evapotranspiration over land can lead to more frequent and more intense periods of agricultural drought.

A general relationship between changes in total precipitation and extreme precipitation does not exist (Seneviratne et al., 2012). Two possible mechanisms controlling short-term extreme precipitation amounts are discussed at length in the literature and are similar to the thermodynamic and dynamical mechanisms detailed above for changes in average precipitation.

The first considers that extreme precipitation events occur when most of the available atmospheric water vapour rapidly precipitates out in a single storm. The maximum amount of water vapour in air (saturation) is determined by the Clausius–Clapeyron relationship. As air temperature increases, this saturated amount of water also increases (Allen and Ingram, 2002; Pall et al., 2007; Allan and Soden, 2008; Kendon et al., 2010). Kunkel et al. (2013) examined the CMIP5 model RCP4.5 and 8.5 projections for changes in maximum water vapour concentrations, a principal factor controlling the probable bound on maximum precipitation, concluding that maximum water vapour changes are comparable to mean water vapour changes but that the potential for changes in dynamical factors is less compelling. Such increases in atmospheric water vapour are expected to increase the intensity of individual precipitation events, but have less impact on their frequency. As a result

projected increases in extreme precipitation may be more reliable than similar projections of changes in mean precipitation in some regions (Kendon et al., 2010).

A second mechanism for extreme precipitation put forth by O'Gorman and Schneider (2009a, 2009b) is that such events are controlled by anomalous horizontal moisture flux convergence and associated convective updrafts which would change in a more complicated fashion in a warmer world (Sugiyama et al., 2010). Emori and Brown (2005) showed that the thermodynamic mechanism dominated over the dynamical mechanism nearly everywhere outside the tropical warm pool. However, Utsumi et al. (2011) used gridded observed daily data to find that daily extreme precipitation monotonically increases with temperature only at high latitudes, with the opposite behaviour in the tropics and a mix in the mid-latitudes. Li et al. (2011a) found that both mechanisms contribute to extreme precipitation in a high-resolution aquaplanet model with updrafts as the controlling element in the tropics and air temperature controlling the mid-latitudes consistent with the results by Chou et al. (2012). Using a high-resolution regional model, Berg et al. (2009) found a seasonal dependence in Europe with the Clausius–Clapeyron relationship providing an upper limit to daily precipitation intensity in winter but water availability rather than storage capacity is the controlling factor in summer. Additionally, Lenderink and Van Meijgaard (2008) found that very short (sub-daily) extreme precipitation events increase at a rate twice the amount predicted by Clausius–Clapeyron scaling in a very high-resolution model over Europe suggesting that both mechanisms can interact jointly. Gastineau and Soden (2009) found in the CMIP3 models that the updrafts associated with the most extreme tropical precipitation events actually weaken despite an increase in the frequency of the heaviest rain rates further complicating simple mechanistic explanations. See also Sections 7.6.5 and 11.3.2.5.2.

Projections of changes in future extreme precipitation may be larger at the regional scales than for future mean precipitation, but natural variability is also larger causing a tendency for signal-to-noise ratios to decrease when considering increasingly extreme metrics. However, mechanisms of natural variability still are a large factor in assessing the robustness of projections (Kendon et al., 2008). In addition, large-scale circulation changes, which are uncertain, could dominate over the above mechanisms depending on the rarity and type of events considered. However, analysis of CMIP3 models suggests circulation changes are potentially insufficient to offset the influence of increasing atmospheric water vapour on extreme precipitation change over Europe at least on large spatial scales (Kendon et al., 2010). An additional shift of the storm track has been shown in models with a better representation of the stratosphere, and this is found to lead to an enhanced increase in extreme rainfall over Europe in winter (Scaife et al., 2012).

Similar to temperature extremes (Section 12.4.3.3), the definition of a precipitation extreme depends very much on context and is often used in discussion of particular climate-related impacts (Seneviratne et al. (2012), Box 3.1). Consistently, climate models project future episodes of more intense precipitation in the wet seasons for most of the land areas, especially in the NH and its higher latitudes, and the monsoon regions of the world, and at a global average scale. The actual magnitude of the projected change is dependent on the model used,

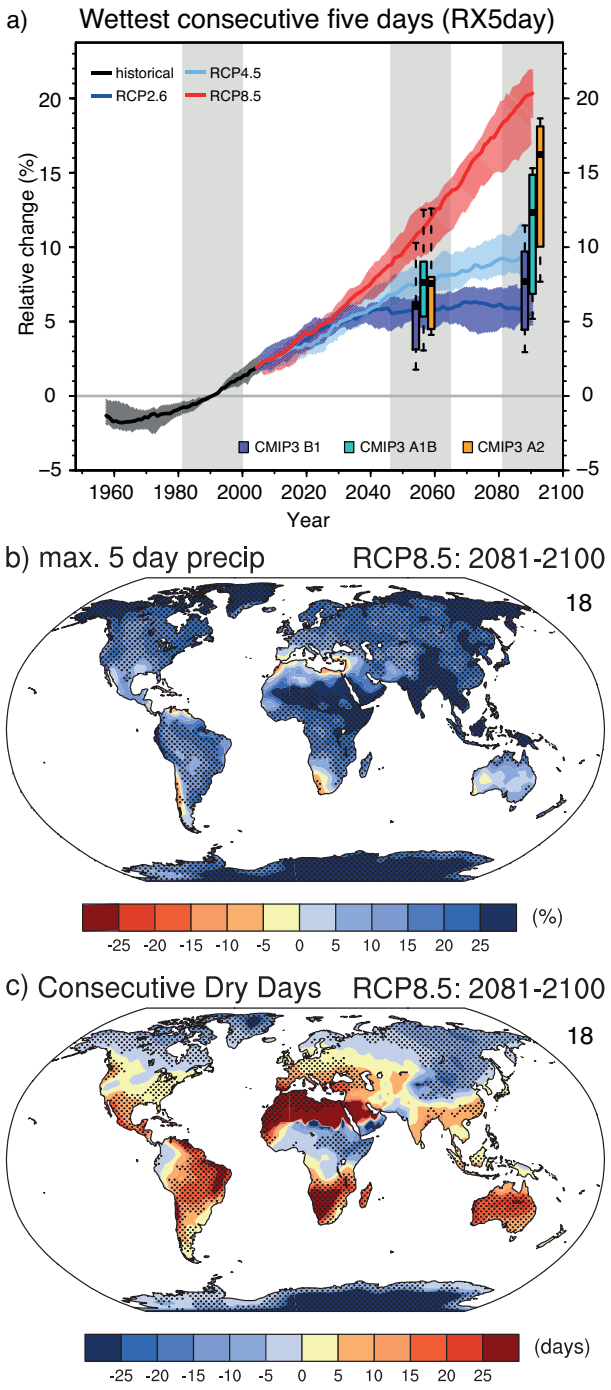

Figure 12.26 | (a, b) Projected percent changes (relative to the 1981–2000 reference period in common with CMIP3) from the CMIP5 models in RX5day, the annual maximum five-day precipitation accumulation. (a) Global average percent change over land regions for the RCP2.6, RCP4.5 and RCP8.5 scenarios. Shading in the time series represents the interquartile ensemble spread (25th and 75th quantiles). The box-and-whisker plots show the interquartile ensemble spread (box) and outliers (whiskers) for 11 CMIP3 model simulations of the SRES scenarios A2 (orange), A1B (cyan) and B1 (purple) globally averaged over the respective future time periods (2046–2065 and 2081–2100) as anomalies from the 1981–2000 reference period. (b) Percent change over the 2081–2100 period in the RCP8.5 scenario. (c) Projected change in annual CDD, the maximum number of consecutive dry days when precipitation is less than 1 mm, over the 2081–2100 period in the RCP8.5 scenario (relative to the 1981–2000 reference period) from the CMIP5 models. Stippling indicates gridpoints with changes that are significant at the 5% level using a Wilcoxon signed-ranked test. (Updated from Sillmann et al. (2013), excluding the FGOALS-s2 model.)

Frequently Asked Questions

FAQ 12.2 | How Will the Earth's Water Cycle Change?

The flow and storage of water in the Earth's climate system are highly variable, but changes beyond those due to natural variability are expected by the end of the current century. In a warmer world, there will be net increases in rainfall, surface evaporation and plant transpiration. However, there will be substantial differences in the changes between locations. Some places will experience more precipitation and an accumulation of water on land. In others, the amount of water will decrease, due to regional drying and loss of snow and ice cover.

The water cycle consists of water stored on the Earth in all its phases, along with the movement of water through the Earth's climate system. In the atmosphere, water occurs primarily as a gas—water vapour—but it also occurs as ice and liquid water in clouds. The ocean, of course, is primarily liquid water, but the ocean is also partly covered by ice in polar regions. Terrestrial water in liquid form appears as surface water—such as lakes and rivers—soil moisture and groundwater. Solid terrestrial water occurs in ice sheets, glaciers, snow and ice on the surface and in permafrost and seasonally frozen soil.

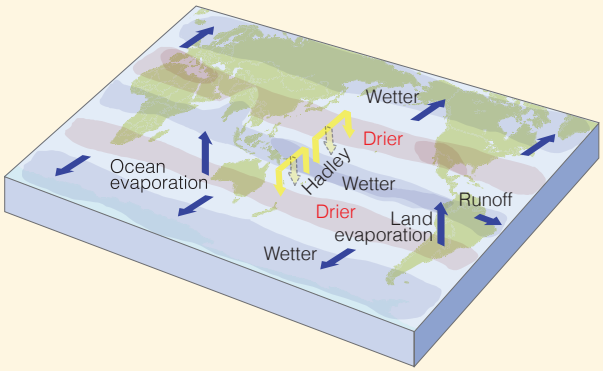
Statements about future climate sometimes say that the water cycle will accelerate, but this can be misleading, for strictly speaking, it implies that the cycling of water will occur more and more quickly with time and at all locations. Parts of the world will indeed experience intensification of the water cycle, with larger transports of water and more rapid movement of water into and out of storage reservoirs. However, other parts of the climate system will experience substantial depletion of water, and thus less movement of water. Some stores of water may even vanish.

As the Earth warms, some general features of change will occur simply in response to a warmer climate. Those changes are governed by the amount of energy that global warming adds to the climate system. Ice in all forms will melt more rapidly, and be less pervasive. For example, for some simulations assessed in this report, summer Arctic sea ice disappears before the middle of this century. The atmosphere will have more water vapour, and observations and model results indicate that it already does. By the end of the 21st century, the average amount of water vapour in the atmosphere could increase by 5 to 25%, depending on the amount of human emissions of greenhouse gases and radiatively active particles, such as smoke. Water will evaporate more quickly from the surface. Sea level will rise due to expansion of warming ocean waters and melting land ice flowing into the ocean (see FAQ 13.2).

These general changes are modified by the complexity of the climate system, so that they should not be expected to occur equally in all locations or at the same pace. For example, circulation of water in the atmosphere, on land and in the ocean can change as climate changes, concentrating water in some locations and depleting it in others. The changes also may vary throughout the year: some seasons tend to be wetter than others. Thus, model simulations assessed in this report show that winter precipitation in northern Asia may increase by more than 50%, whereas summer precipitation there is projected to hardly change. Humans also intervene directly in the water cycle, through water management and changes in land use. Changing population distributions and water practices would produce further changes in the water cycle.

Water cycle processes can occur over minutes, hours, days and longer, and over distances from metres to kilometres and greater. Variability on these scales is typically greater than for temperature, so climate changes in precipitation are harder to discern. Despite this complexity, projections of future climate show changes that are common across many models and climate forcing scenarios. Similar changes were reported in the AR4. These results collectively suggest well understood mechanisms of change, even if magnitudes vary with model and forcing. We focus here on changes over land, where changes in the water cycle have their largest impact on human and natural systems.

Projected climate changes from simulations assessed in this report (shown schematically in FAQ 12.2, Figure 1) generally show an increase in precipitation in parts of the deep tropics and polar latitudes that could exceed 50% by the end of the 21st century under the most extreme emissions scenario. In contrast, large areas of the subtropics could have decreases of 30% or more. In the tropics, these changes appear to be governed by increases in atmospheric water vapour and changes in atmospheric circulation that further concentrate water vapour in the tropics and thus promote more tropical rainfall. In the subtropics, these circulation changes simultaneously promote less rainfall despite warming in these regions. Because the subtropics are home to most of the world's deserts, these changes imply increasing aridity in already dry areas, and possible expansion of deserts. *(continued on next page)*



FAQ 12.2 (continued)

Increases at higher latitudes are governed by warmer temperatures, which allow more water in the atmosphere and thus, more water that can precipitate. The warmer climate also allows storm systems in the extratropics to transport more water vapour into the higher latitudes, without requiring substantial changes in typical wind strength. As indicated above, high latitude changes are more pronounced during the colder seasons.

Whether land becomes drier or wetter depends partly on precipitation changes, but also on changes in surface evaporation and transpiration from plants (together called evapotranspiration). Because a warmer atmosphere can have more water vapour, it can induce greater evapotranspiration, given sufficient terrestrial water. However, increased carbon dioxide in the atmosphere reduces a plant's tendency to transpire into the atmosphere, partly counteracting the effect of warming.

In the tropics, increased evapotranspiration tends to counteract the effects of increased precipitation on soil moisture, whereas in the subtropics, already low amounts of soil moisture allow for little change in evapotranspiration. At higher latitudes, the increased precipitation generally outweighs increased evapotranspiration in projected climates, yielding increased annual mean runoff, but mixed changes in soil moisture. As implied by circulation changes in FAQ 12.2, Figure 1, boundaries of high or low moisture regions may also shift.

A further complicating factor is the character of rainfall. Model projections show rainfall becoming more intense, in part because more moisture will be present in the atmosphere. Thus, for simulations assessed in this report, over much of the land, 1-day precipitation events that currently occur on average every 20 years could occur every 10 years or even more frequently by the end of the 21st century. At the same time, projections also show that precipitation events overall will tend to occur less frequently. These changes produce two seemingly contradictory effects: more intense downpours, leading to more floods, yet longer dry periods between rain events, leading to more drought.

FAQ 12.2, Figure 1 | Schematic diagram of projected changes in major components of the water cycle. The blue arrows indicate major types of water movement changes through the Earth's climate system: poleward water transport by extratropical winds, evaporation from the surface and runoff from the land to the oceans. The shaded regions denote areas more likely to become drier or wetter. Yellow arrows indicate an important atmospheric circulation change by the Hadley Circulation, whose upward motion promotes tropical rainfall, while suppressing subtropical rainfall. Model projections indicate that the Hadley Circulation will shift its downward branch poleward in both the Northern and Southern Hemispheres, with associated drying. Wetter conditions are projected at high latitudes, because a warmer atmosphere will allow greater precipitation, with greater movement of water into these regions.

At high latitudes and at high elevation, further changes occur due to the loss of frozen water. Some of these are resolved by the present generation of global climate models (GCMs), and some changes can only be inferred because they involve features such as glaciers, which typically are not resolved or included in the models. The warmer climate means that snow tends to start accumulating later in the fall, and melt earlier in the spring. Simulations assessed in this report show March to April snow cover in the Northern Hemisphere is projected to decrease by approximately 10 to 30% on average by the end of this century, depending on the greenhouse gas scenario. The earlier spring melt alters the timing of peak springtime flow in rivers receiving snowmelt. As a result, later flow rates will decrease, potentially affecting water resource management. These features appear in GCM simulations.

Loss of permafrost will allow moisture to seep more deeply into the ground, but it will also allow the ground to warm, which could enhance evapotranspiration. However, most current GCMs do not include all the processes needed to simulate well permafrost changes. Studies analysing soils freezing or using GCM output to drive more detailed land models suggest substantial permafrost loss by the end of this century. In addition, even though current GCMs do not explicitly include glacier evolution, we can expect that glaciers will continue to recede, and the volume of water they provide to rivers in the summer may dwindle in some locations as they disappear. Loss of glaciers will also contribute to a reduction in springtime river flow. However, if annual mean precipitation increases—either as snow or rain—then these results do not necessarily mean that annual mean river flow will decrease.

but there is strong agreement across the models over the direction of change (Tebaldi et al., 2006; Goubanova and Li, 2007; Chen and Knutson, 2008; Haugen and Iversen, 2008; May, 2008b; Kysely and Beranova, 2009; Min et al., 2011; Sillmann et al., 2013). Regional details are less robust in terms of the relative magnitude of changes but remain in good accord across models in terms of the sign of the change and the large-scale geographical patterns (Meehl et al., 2005a; CCSP, 2008a). In semi-arid regions of the midlatitudes and subtropics such as the Mediterranean, the southwest USA, southwestern Australia, southern Africa and a large portion of South America, the tendency manifested in the majority of model simulations is for longer dry periods and is consistent with the average decreases shown in Figure 12.22. Figure 12.26 shows projected percent changes in RX5day, the annual maximum of consecutive 5-day precipitation over land regions obtained from the CMIP5 models (Box 2.4, Table 1). Globally averaged end of 21st century changes over land range from 5% (RCP2.6) to 20% (RCP8.5) more precipitation during very wet 5-day periods. Results from the CMIP3 models are shown for comparison (see Section 12.4.9). Locally, the few regions where this index of extreme precipitation decreases in the late 21st century RCP8.5 projection coincide with areas of robust decreases in the mean precipitation of Figure 12.22.

Drought is discussed extensively in the SREX report (Seneviratne et al., 2012) and the conclusions about future drought risk described there based on CMIP3 models are reinforced by the CMIP5 models. As noted in the SREX reports, assessments of changes in drought characteristics with climate change should be made in the context of specific impacts questions. The risk of future agricultural drought episodes is increased in the regions of robust soil moisture decrease described in Section 12.4.5.3 and shown in Figure 12.23. Other measures in the literature of future agricultural drought are largely focussed on the Palmer Drought Severity Index (Wehner et al., 2011; Schwalm et al., 2012; Dai, 2013) and project 'extreme' drought as the normal climatological state by the end of the 21st century under the high emission scenarios in many mid-latitude locations. However, this measure of agricultural drought has been criticized as overly sensitive to increased temperatures due to a simplified soil moisture model (Hoerling et al., 2012). The consecutive dry-day index (CDD) is the length of the longest period of consecutive days with precipitation less than 1 mm (Box 2.4, Table 1). CMIP5 projected changes in CDD over the 2081–2100 period under the RCP8.5 scenario (relative to the 1981–2000 reference period in common with CMIP3) from the CMIP5 models are shown in Figure 12.26c and exhibit patterns similar to projected changes in both precipitation and soil moisture (Sillmann et al., 2013). Substantial increases in this measure of meteorological drought are projected in the Mediterranean, Central America, Brazil, South Africa and Australia while decreases are projected in high northern latitudes.

Truly rare precipitation events can cause very significant impacts. The statistics of these events at the tails of the precipitation distribution are well described by Extreme Value (EV) Theory although there are significant biases in the direct comparison of gridded model output and actual station data (Smith et al., 2009). There is also strong evidence that model resolution plays a key role in replicating EV quantities estimated from gridded observational data, suggesting that high-resolution models may provide somewhat more confidence in projection of changes in rare precipitation events (Fowler et al., 2007a; Wehner et al., 2011). Figure 12.27 shows the late 21st century changes per degree Celsius in local warming in 20-year return values of annual maximum daily precipitation relative to the late 20th century (left) and the associated return periods of late 20th century 20-year return values at the end of the 21st century from the CMIP5 models. Across future emission scenarios, the global average of the CMIP5 multi-model median return value sensitivity is an increase of 5.3% $°C^{-1}$ (Kharin et al., 2013). The CMIP5 land average is close to the CMIP3 value of 4% $°C^{-1}$ reported by Min et al. (2011) for a subset of CMIP3 models. Corresponding with this change, the global average of return periods of late 20th century 20-year return values is reduced from 20 years to 14 years for a 1°C local warming. Return periods are projected to be reduced by about 10 to 20% $°C^{-1}$ over the most of the mid-latitude land masses with larger reductions over wet tropical regions (Kharin et al., 2013). Hence, extreme precipitation events will *very likely* be more intense

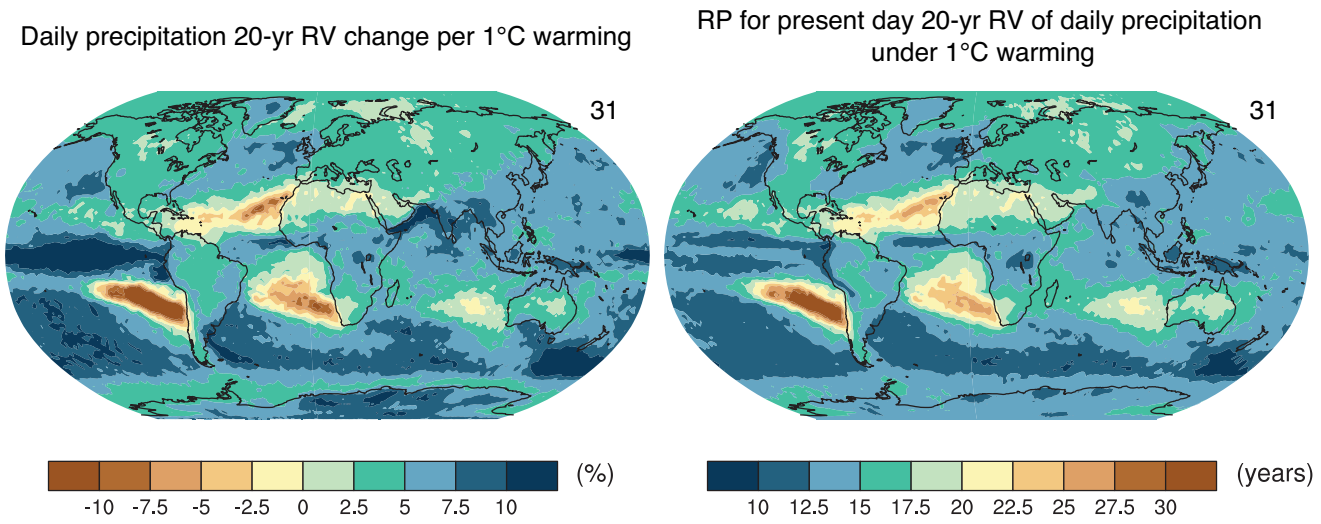


Figure 12.27 | (Left) The CMIP5 2081–2100 multi-model ensemble median percent change in 20-year return values of annual maximum daily precipitation per 1°C of local warming relative to the 1986–2005 reference period. (Right) The average 2081–2100 CMIP5 multi-model ensemble median of the return periods (years) of 1986–2005 20-year return values of annual maximum daily precipitation corresponding to 1°C of local warming. Regions of no change would have return periods of 20 years.

and more frequent in these regions in a warmer climate. Reductions in return values (or equivalently, increases in return period) are confined to convergent oceanic regions where circulation changes have reduced the available water vapour.

Severe thunderstorms, associated with large hail, high winds, and tornadoes, are another example of extreme weather associated with the water cycle. The large-scale environments in which they occur are characterized by large Convective Available Potential Energy (CAPE) and deep tropospheric wind shear (Brooks et al., 2003; Brooks, 2009). Del Genio et al. (2007), Trapp et al. (2007, 2009), and Van Klooster and Roebber (2009) found a general increase in the energy and decrease in the shear terms from the late 20th century to the late 21st century over the USA using a variety of regional model simulations embedded in global model SRES scenario simulations. The relative change between these two competing factors would tend to favour more environments that would support severe thunderstorms, providing storms are initiated. Trapp et al. (2009), for example, found an increase in favourable thunderstorm conditions for all regions of the USA east of the Rocky Mountains. Large variability in both the energy and shear terms means that statistical significance is not reached until late in the 21st century under high forcing scenarios. One way of assessing the possibility of a change in the frequency of future thunderstorms is to look at historical records of observed tornado, hail and wind occurrence with respect to the environmental conditions (Brooks, 2013). This indicates that an increase in the fraction of severe thunderstorms containing non-tornadic winds would be consistent with the model projections of increased energy and decreased shear, but there has not been enough research to make a firm conclusion regarding future changes in frequency or magnitude.

Less work has been done on projected changes outside of the USA. Marsh et al. (2009) found that mean energy decreased in the warm season in Europe while it increased in the cool season. Even though the energy decreases in the warm season, the number of days with favourable environments for severe thunderstorms increases because of an increasing number of days with relatively large values of available energy. For Europe, with the Mediterranean Sea and Sahara Desert to the south, questions remain about changes in boundary layer moisture, a main driver of the energy term. Niall and Walsh (2005) examined changes in CAPE, which may be associated with hailstorm occurrence in southeastern Australia using a global model, and found little change under warmer conditions. Leslie et al. (2008) reconsidered the southeastern Australia hail question by nesting models with 1 km horizontal grid spacing and using sophisticated microphysical parameterizations and found an increase in the frequency of large hail by 2050 under the SRES A1B scenario, but with extremely large internal variability in the environments and hail size.

Overall, for all parts of the world studied, the results are suggestive of a trend toward environments favouring more severe thunderstorms, but the small number of analyses precludes any likelihood estimate of this change.

12.4.6 Changes in Cryosphere

12.4.6.1 Changes in Sea Ice Cover

Based on the analysis of CMIP3 climate change simulations (e.g., Arzel et al., 2006; Zhang and Walsh, 2006), the AR4 concludes that the Arctic and Antarctic sea ice covers are projected to shrink in the 21st century under all SRES scenarios, with a large range of model responses (Meehl et al., 2007b). It also stresses that, in some projections, the Arctic Ocean becomes almost entirely ice-free in late summer during the second half of the 21st century. These conclusions were confirmed by further analyses of the CMIP3 archives (e.g., Stroeve et al., 2007; Bracegirdle et al., 2008; Lefebvre and Goosse, 2008; Boé et al., 2009b; Sen Gupta et al., 2009; Wang and Overland, 2009; Zhang, 2010b; NRC, 2011; Körper et al., 2013). Figures 12.28 and 12.29 and the studies of Maksym et al. (2012), Massonnet et al. (2012), Stroeve et al. (2012) and Wang and Overland (2012) show that the CMIP5 AOGCMs/ESMs as a group also project decreases in sea ice extent through the end of this century in both hemispheres under all RCPs. However, as in the case of CMIP3, the inter-model spread is considerable.

In the NH, in accordance with CMIP3 results, the absolute rate of decrease of the CMIP5 multi-model mean sea ice areal coverage is greatest in September. The reduction in sea ice extent between the time periods 1986–2005 and 2081–2100 for the CMIP5 multi-model average ranges from 8% for RCP2.6 to 34% for RCP8.5 in February and from 43% for RCP2.6 to 94% for RCP8.5 in September. *Medium confidence* is attached to these values as projections of sea ice extent decline in the real world due to errors in the simulation of present-day sea ice extent (mean and trends—see Section 9.4.3) and because of the large spread of model responses. About 90% of the available CMIP5 models reach nearly ice-free conditions (sea ice extent less than 1×10^6 km^2 for at least 5 consecutive years) during September in the Arctic before 2100 under RCP8.5 (about 45% under RCP4.5). By the end of the 21st century, the decrease in multi-model mean sea ice volume ranges from 29% for RCP2.6 to 73% for RCP8.5 in February and from 54% for RCP2.6 to 96% for RCP8.5 in September. *Medium confidence* is attached to these values as projections of the real world sea ice volume. In February, these percentages are much higher than the corresponding ones for sea ice extent, which is indicative of a substantial sea ice thinning.

A frequent criticism of the CMIP3 models is that, as a group, they strongly underestimate the rapid decline in summer Arctic sea ice extent observed during the past few decades (e.g., Stroeve et al., 2007; Winton, 2011), which suggests that the CMIP3 projections of summer Arctic sea ice areal coverage might be too conservative. As shown in Section 9.4.3 and Figure 12.28b, the magnitude of the CMIP5 multi-model mean trend in September Arctic sea ice extent over the satellite era is more consistent with, but still underestimates, the observed one (see also Massonnet et al., 2012; Stroeve et al., 2012; Wang and Overland, 2012; Overland and Wang, 2013). Owing to the shortness of the observational record, it is difficult to ascertain the relative influence of natural variability on this trend. This hinders the comparison between modelled and observed trends, and hence the estimate of the sensitivity of the September Arctic sea ice extent to global surface temperature change (i.e., the decrease in sea ice extent per degree global

warming) (Kay et al., 2011; Winton, 2011; Mahlstein and Knutti, 2012). This sensitivity may be crucial for determining future sea ice losses. Indeed, a clear relationship exists at longer than decadal time scales in climate change simulations between the annual mean or September mean Arctic sea ice extent and the annual mean global surface temperature change for ice extents larger than ~1 × 10^6 km^2 (e.g., Ridley et al., 2007; Zhang, 2010b; NRC, 2011; Winton, 2011; Mahlstein and Knutti, 2012). This relationship is illustrated in Figure 12.30 for both CMIP3 and CMIP5 models. From this figure, it can be seen that the sea ice sensitivity varies significantly from model to model and is generally larger and in better agreement among models in CMIP5.

A complete and detailed explanation for what controls the range of Arctic sea ice responses in models over the 21st century remains elusive, but the Arctic sea ice provides an example where process-based constraints can be used to reduce the spread of model projections (Overland et al., 2011; Collins et al., 2012; Hodson et al., 2012). For CMIP3 models, results indicate that the changes in Arctic sea ice mass budget over the 21st century are related to the late 20th century mean sea ice thickness distribution (Holland et al., 2010), average sea ice thickness (Bitz, 2008; Hodson et al., 2012), fraction of thin ice cover (Boé et al., 2009b) and oceanic heat transport to the Arctic (Mahlstein and Knutti, 2011). For CMIP5 models, Massonnet et al. (2012) showed that the time needed for the September Arctic sea ice areal coverage to drop below a certain threshold is highly correlated with the September sea ice extent and annual mean sea ice volume averaged over the past several decades (Figure 12.31a, b). The timing of a seasonally ice-free Arctic Ocean or the fraction of remaining sea ice in September at any time during the 21st century were also found to correlate with the past trend in September Arctic sea ice extent and the amplitude of the mean seasonal cycle of sea ice extent (Boé et al., 2009b; Collins et al., 2012; Massonnet et al., 2012) (Figure 12.31c, d). All these empirical

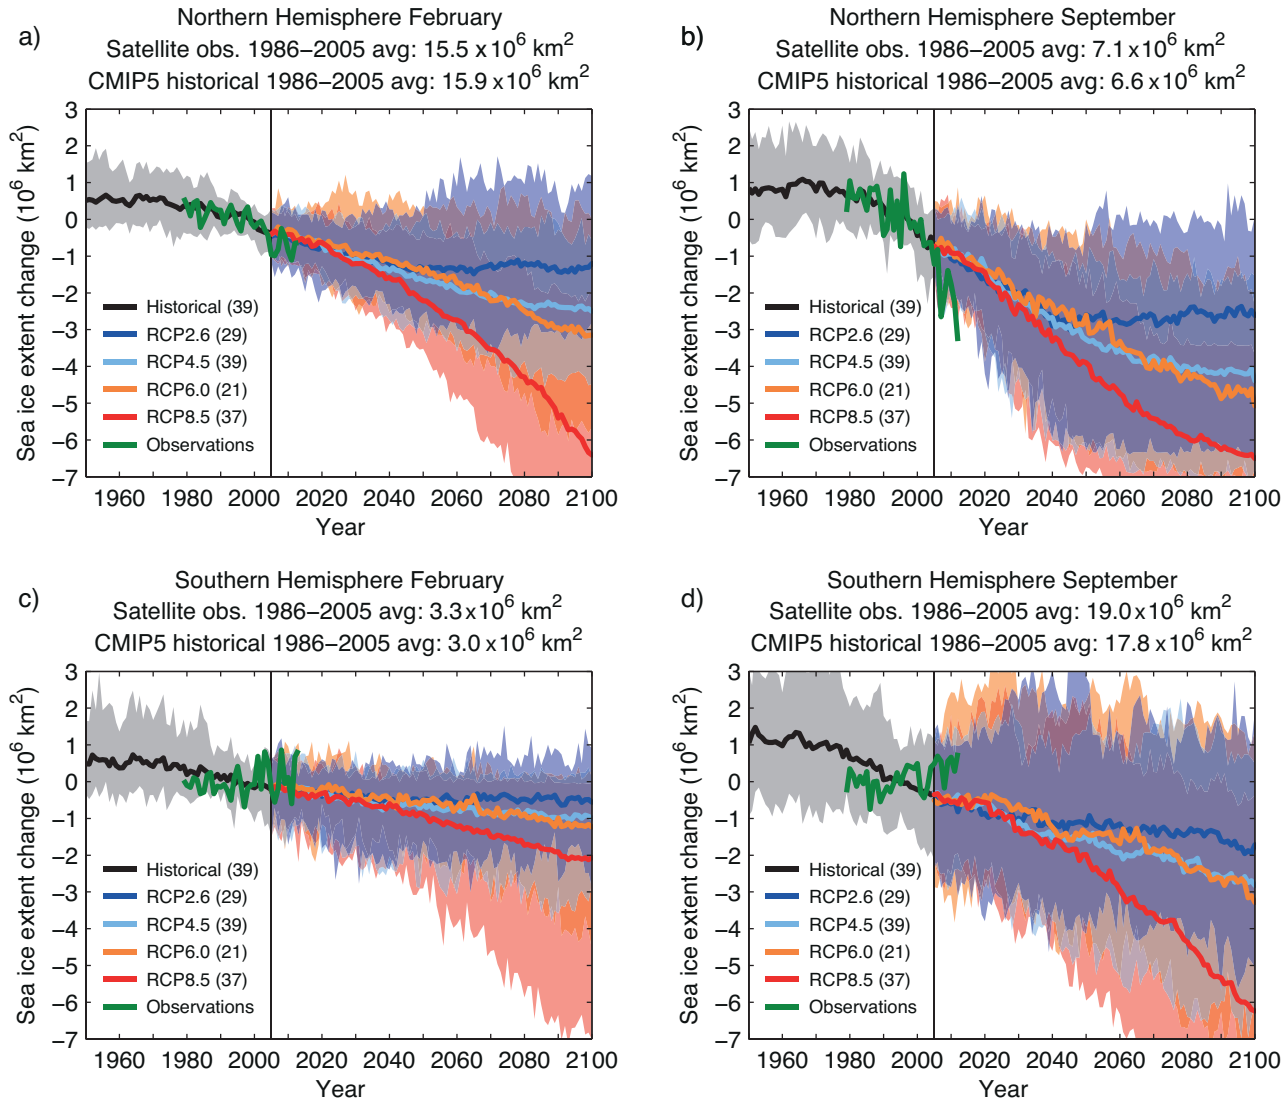

Figure 12.28 | Changes in sea ice extent as simulated by CMIP5 models over the second half of the 20th century and the whole 21st century under RCP2.6, RCP4.5, RCP6.0 and RCP8.5 for (a) Northern Hemisphere February, (b) Northern Hemisphere September, (c) Southern Hemisphere February and (d) Southern Hemisphere September. The solid curves show the multi-model means and the shading denotes the 5 to 95% range of the ensemble. The vertical line marks the end of CMIP5 historical climate change simulations. One ensemble member per model is taken into account in the analysis. Sea ice extent is defined as the total ocean area where sea ice concentration exceeds 15% and is calculated on the original model grids. Changes are relative to the reference period 1986–2005. The number of models available for each RCP is given in the legend. Also plotted (solid green curves) are the satellite data of Comiso and Nishio (2008, updated 2012) over 1979–2012.

relationships can be understood on simple physical grounds (see the aforementioned references for details).

These results lend support for weighting/recalibrating the models based on their present-day Arctic sea ice simulations. Today, the optimal approach for constraining sea ice projections from climate models is unclear, although one notes that these methods should have a credible underlying physical basis in order to increase confidence in their results (see Section 12.2). In addition, they should account for the potentially large imprint of natural variability on both observations and model simulations when these two sources of information are to be compared (see Section 9.8.3). This latter point is particularly critical if the past sea ice trend or sensitivity is used in performance metrics given the relatively short observational period (Kay et al., 2011; Overland et al., 2011; Mahlstein and Knutti, 2012; Massonnet et al., 2012; Stroeve et al., 2012). A number of studies have applied such metrics to the CMIP3 and CMIP5 models. Stroeve et al. (2007) and Stroeve et al. (2012) rejected several CMIP3 and CMIP5 models, respectively, on

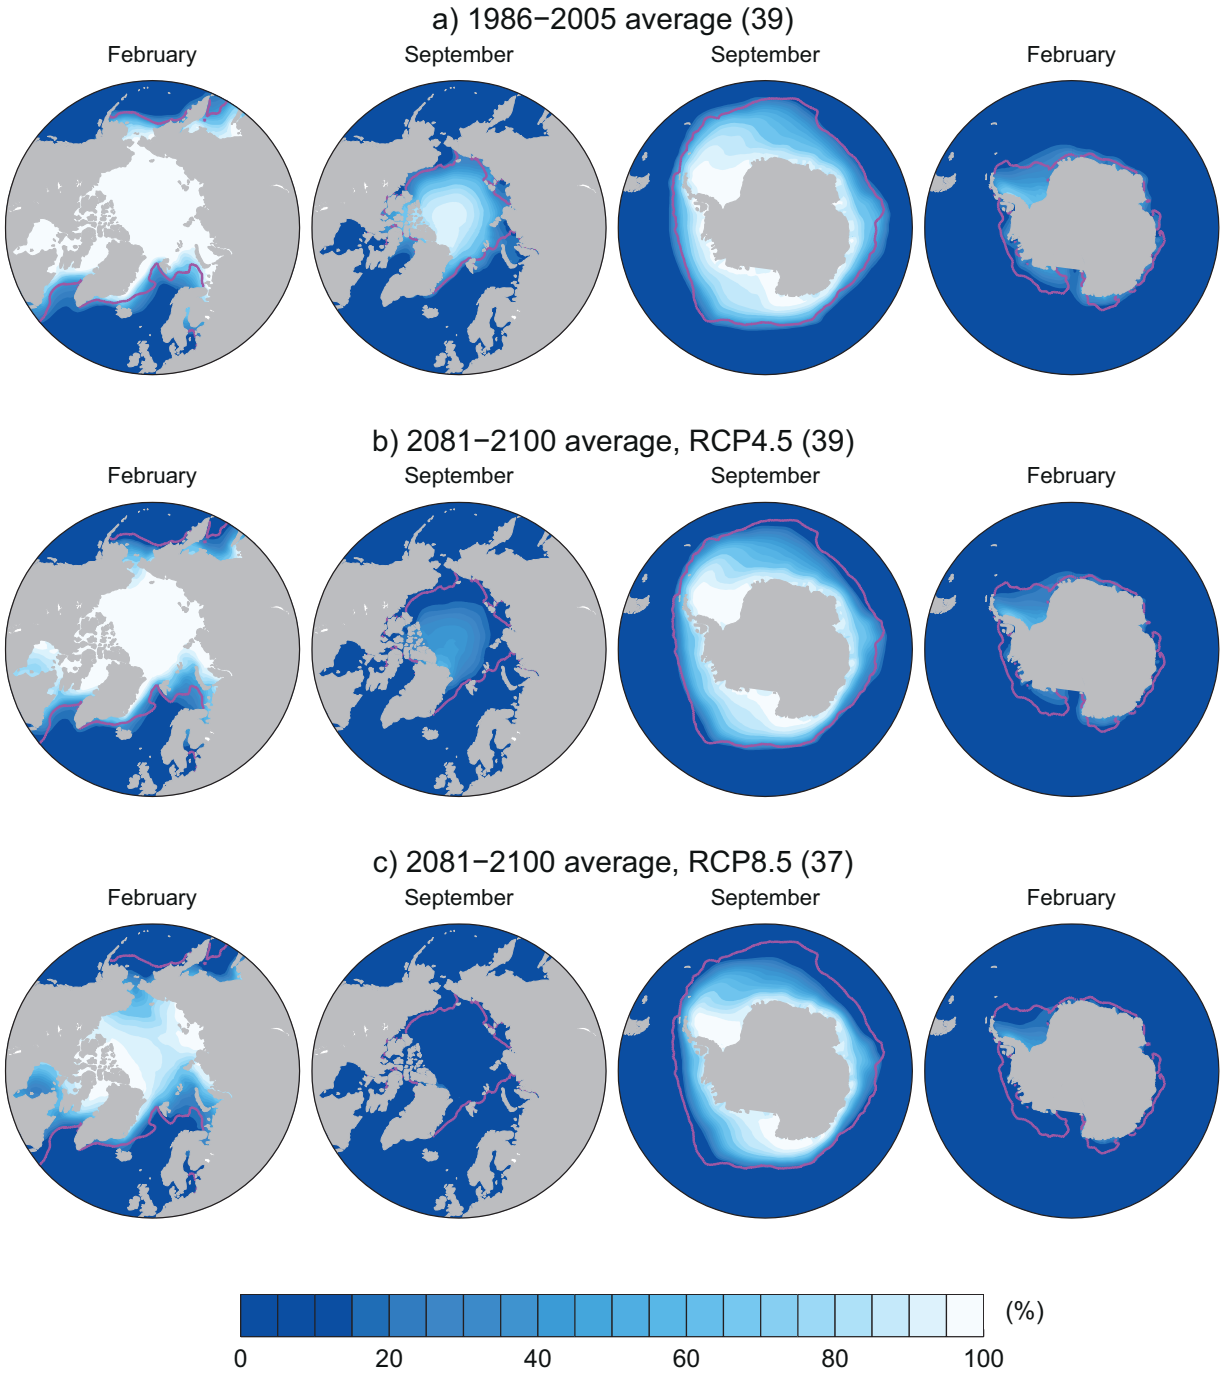

Figure 12.29 | February and September CMIP5 multi-model mean sea ice concentrations (%) in the Northern and Southern Hemispheres for the periods (a) 1986–2005, (b) 2081–2100 under RCP4.5 and (c) 2081–2100 under RCP8.5. The model sea ice concentrations are interpolated onto a 1° × 1° regular grid. One ensemble member per model is taken into account in the analysis, and the multi-model mean sea ice concentration is shown where it is larger than 15%. The number of models available for each RCP is given in parentheses. The pink lines indicate the observed 15% sea ice concentration limits averaged over 1986–2005 (Comiso and Nishio, 2008, updated 2012).

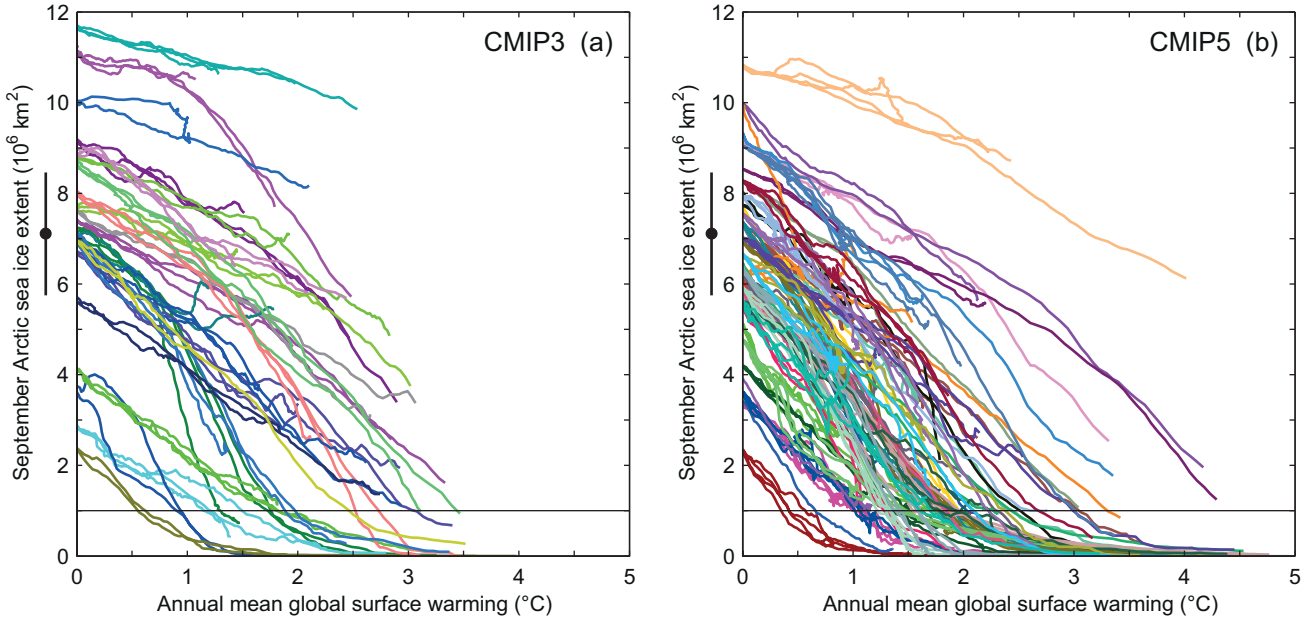

Figure 12.30 | September Arctic sea ice extent as a function of the annual mean global surface warming relative to the period 1986–2005 for (a) CMIP3 models (all SRES scenarios) and (b) CMIP5 models (all RCPs). The ice extents and global temperatures are computed on a common latitude-longitude grid for CMIP3 and on the original model grids for CMIP5. One ensemble member per model is taken into account in the analysis. A 21-year running mean is applied to the model output. The full black circle and vertical bar on the left-hand side of the *y*-axis indicate the mean and ±2 standard deviations about the mean of the observed September Arctic sea ice extent over 1986–2005, respectively (Comiso and Nishio, 2008, updated 2012). The horizontal line corresponds to a nearly ice-free Arctic Ocean in September.

the basis of their simulated late 20th century mean September Arctic sea ice extent. Wang and Overland (2009) selected a subset of CMIP3 models (and Wang and Overland (2012) did the same for the CMIP5 models) based on their fidelity to the observed mean seasonal cycle of Arctic sea ice extent in the late 20th century and then scaled the chosen models to the recently observed September sea ice extent. Zhang (2010b) retained a number of CMIP3 models based on the regression between summer sea ice loss and Arctic surface temperature change. Boé et al. (2009b) and Mahlstein and Knutti (2012) did not perform a model selection but rather recalibrated the CMIP3 Arctic sea ice projections on available observations of September Arctic sea ice trend and sensitivity to global surface temperature change, respectively. Finally, Massonnet et al. (2012) selected a subset of CMIP5 models on the basis of the four relationships illustrated in Figure 12.31a–d.

These various methods all suggest a faster rate of summer Arctic sea ice decline than the multi-model mean. Although they individually provide a reduced range for the year of near disappearance of the September Arctic sea ice compared to the original CMIP3/CMIP5 multi-model ensemble, they lead to different timings (Overland and Wang, 2013). Consequently, the time interval obtained when combining all these studies remains wide: 2020–2100$^+$ (2100$^+$ = not before 2100) for the SRES A1B scenario and RCP4.5 (Stroeve et al., 2007, 2012; Boé et al., 2009b; Wang and Overland, 2009, 2012; Zhang, 2010b; Massonnet et al., 2012) and 2020–2060 for RCP8.5 (Massonnet et al., 2012; Wang and Overland, 2012). The method proposed by Massonnet et al. (2012) is applied here to the full set of models that provided the CMIP5 database with sea ice output. The natural variability of each of the four diagnostics shown in Figure 12.31a–d is first estimated by averaging over all available models with more than one ensemble member the diagnostic standard deviations derived from the model ensemble members. Then, for each model, a ±2 standard deviation interval is constructed around the ensemble mean or single realization of the diagnostic considered. A model is retained if, for each diagnostic, either this interval overlaps a ±20% interval around the observed/reanalysed value of the diagnostic or at least one ensemble member from that model gives a value for the diagnostic that falls within ±20% of the observational/reanalysed data. The outcome is displayed in Figure 12.31e for RCP8.5. Among the five selected models (ACCESS1.0, ACCESS1.3, GFDL-CM3, IPSL-CM5A-MR, MPI-ESM-MR), four project a nearly ice-free Arctic Ocean in September before 2050 (2080) for RCP8.5 (RCP4.5), the earliest and latest years of near disappearance of the sea ice pack being about 2040 and about 2060 (about 2040 and 2100$^+$), respectively. It should be mentioned that Maslowski et al. (2012) projected that it would take only until about 2016 to reach a nearly ice-free Arctic Ocean in summer, based on a linear extrapolation into the future of the recent sea ice volume trend from a hindcast simulation conducted with a regional model of the Arctic sea ice–ocean system. However, such an extrapolation approach is problematic as it ignores the negative feedbacks that can occur when the sea ice cover becomes thin (e.g., Bitz and Roe, 2004; Notz, 2009) and neglects the effect of year-to-year or longer-term variability (Overland and Wang, 2013). Mahlstein and Knutti (2012) encompassed the dependence of sea ice projections on the forcing scenario by determining the annual mean global surface warming threshold for nearly ice-free conditions in September. Their best estimate of ~2°C above the present derived from both CMIP3 models and observations is consistent with the 1.6 to 2.1°C range (mean value: 1.9°C) obtained from the CMIP5 model subset shown in Figure 12.31e (see also Figure 12.30b). The reduction in September Arctic sea ice extent by the end of the 21st century, averaged over this subset of models, ranges from 56% for RCP2.6 to 100% for RCP8.5.

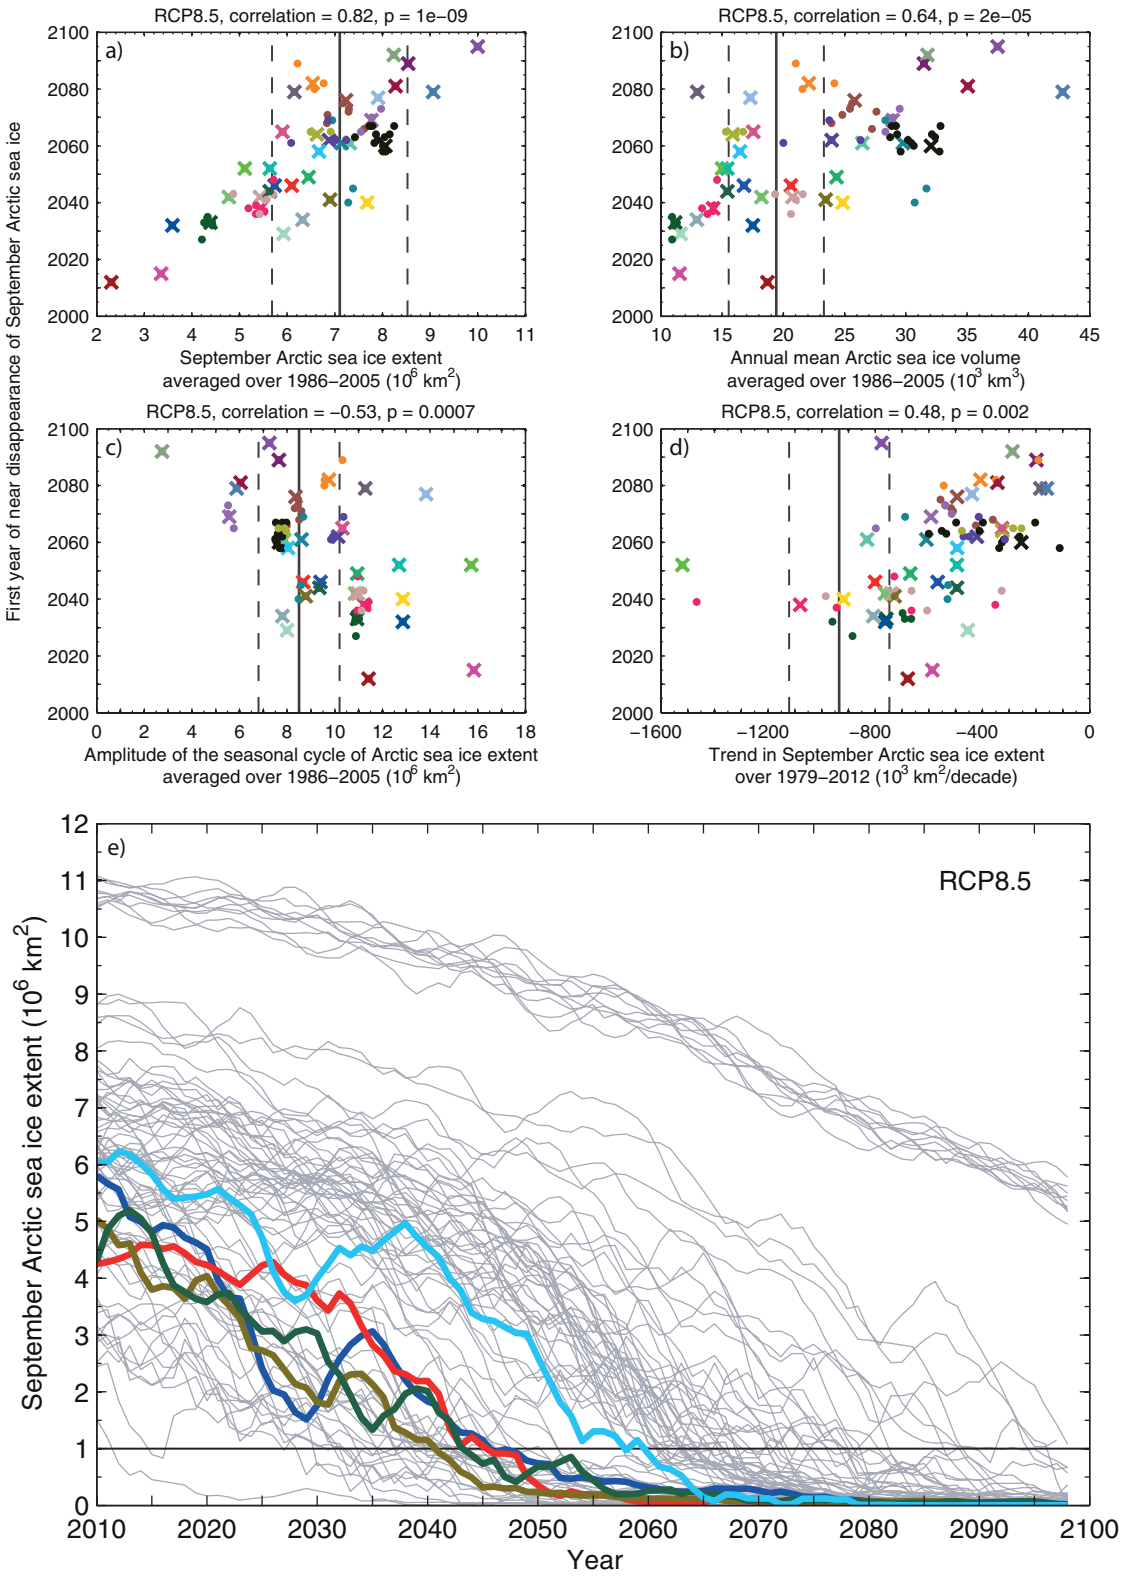

Figure 12.31 | (a–d) First year during which the September Arctic sea ice extent falls below 1 × 10^6 km^2 in CMIP5 climate projections (37 models, RCP8.5) as a function of (a) the September Arctic sea ice extent averaged over 1986–2005, (b) the annual mean Arctic sea ice volume averaged over 1986–2005, (c) the amplitude of the 1986–2005 mean seasonal cycle of Arctic sea ice extent and (d) the trend in September Arctic sea ice extent over 1979–2012. The sea ice diagnostics displayed are calculated on the original model grids. The correlations and one-tailed *p*-values are computed from the multi-member means for models with several ensemble members (coloured crosses), but the ensemble members of individual models are also depicted (coloured dots). The vertical solid and dashed lines show the corresponding observations or bias-adjusted PIOMAS (Pan-Arctic Ice-Ocean Modelling and Assimilation System) reanalysis data (a, c and d: Comiso and Nishio, 2008, updated 2012; b: Schweiger et al., 2011) and the ±20% interval around these data, respectively. (e) Time series of September Arctic sea ice extent (5-year running mean) as simulated by all CMIP5 models and their ensemble members under RCP8.5 (thin curves). The thick, coloured curves correspond to a subset of five CMIP5 models selected on the basis of panels a–d following Massonnet et al. (2012) (see text for details). Note that each of these models provides only one ensemble member for RCP8.5.

In light of all these results, it is *very likely* that the Arctic sea ice cover will continue to shrink and thin all year round during the 21st century as the annual mean global surface temperature rises. It is also *likely* that the Arctic Ocean will become nearly ice-free in September before the middle of the century for high GHG emissions such as those corresponding to RCP8.5 (*medium confidence*). The potential irreversibility of the Arctic sea ice loss and the possibility of an abrupt transition toward an ice-free Arctic Ocean are discussed in Section 12.5.5.7.

In the SH, the decrease in sea ice extent between 1986–2005 and 2081–2100 projected by the CMIP5 models as a group varies from 16% for RCP2.6 to 67% for RCP8.5 in February and from 8% to 30% in September. In contrast with the NH, the absolute rate of decline is greatest in wintertime. Eisenman et al. (2011) argue that this hemispheric asymmetry in the seasonality of sea ice loss is fundamentally related to the geometry of coastlines. For each forcing scenario, the relative changes in multi-model mean February and September Antarctic sea ice volumes by the end of the century are of the same order as the corresponding ones for sea ice extent. About 75% of the available CMIP5 models reach a nearly ice-free state in February within this century under RCP8.5 (about 60% under RCP4.5). For RCP8.5, only small portions of the Weddell and Ross Seas stay ice-covered in February during 2081–2100 in those models that do not project a seasonally ice-free Southern Ocean (see Figure 12.29c). Nonetheless, there is *low confidence* in these Antarctic sea ice projections because of the wide range of model responses and the inability of almost all of the models to reproduce the mean seasonal cycle, interannual variability and overall increase of the Antarctic sea ice areal coverage observed during the satellite era (see Section 9.4.3; Maksym et al., 2012; Turner et al., 2013; Zunz et al., 2013).

12.4.6.2 Changes in Snow Cover and Frozen Ground

Excluding ice sheets and glaciers, analyses of seasonal snow cover changes generally focus on the NH, where the configuration of the continents on the Earth induces a larger maximum seasonal snow cover extent (SCE) and a larger sensitivity of SCE to climate changes. Seasonal snow cover extent and snow water equivalent (SWE) respond to both temperature and precipitation. At the beginning and the end of the snow season, SCE decreases are closely linked to a shortening of the seasonal snow cover duration, while SWE is more sensitive to snowfall amount (Brown and Mote, 2009). Future widespread reductions of SCE, particularly in spring, are simulated by the CMIP3 models (Roesch, 2006; Brown and Mote, 2009) and confirmed by the CMIP5 ensemble (Brutel-Vuilmet et al., 2013). The NH spring (March-April average) snow cover area changes are coherent in the CMIP5 models although there is considerable scatter. Relative to the 1986–2005 reference period, the CMIP5 models simulate a weak decrease of about 7 ± 4% (one-σ inter-model dispersion) for RCP2.6 during the last two decades of the 21st century, while SCE decreases of about 13 ± 4% are simulated for RCP4.5, 15 ± 5% for RCP6.0, and 25 ± 8% for RCP8.5 (Figure 12.32). There is *medium confidence* in these numbers because of the considerable inter-model scatter mentioned above and because snow processes in global climate models are strongly simplified.

Projections for the change in annual maximum SWE are more mixed. Warming decreases SWE both by reducing the fraction of precipitation that falls as snow and by increasing snowmelt, but projected increases in precipitation over much of the northern high latitudes during winter months act to increase snow amounts. Whether snow covering the ground will become thicker or thinner depends on the balance between these competing factors. Both in the CMIP3 (Räisänen, 2008) and in the CMIP5 models (Brutel-Vuilmet et al., 2013), annual maximum SWE tends to increase or only marginally decrease in the coldest

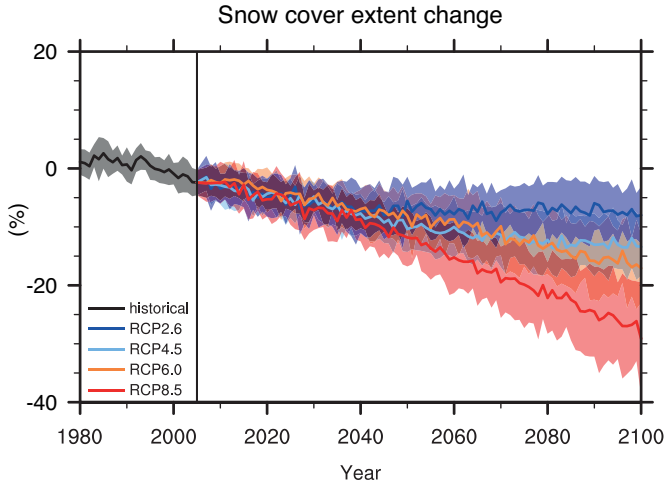

Figure 12.32 | Northern Hemisphere spring (March to April average) snow cover extent change (in %) in the CMIP5 ensemble, relative to the simulated extent for the 1986–2005 reference period. Thick lines mark the multi-model average, shading indicates the inter-model spread (one standard deviation). The observed March to April average snow cover extent for the 1986–2005 reference period is $32.6 \cdot 10^6$ km^2 (Brown and Robinson, 2011).

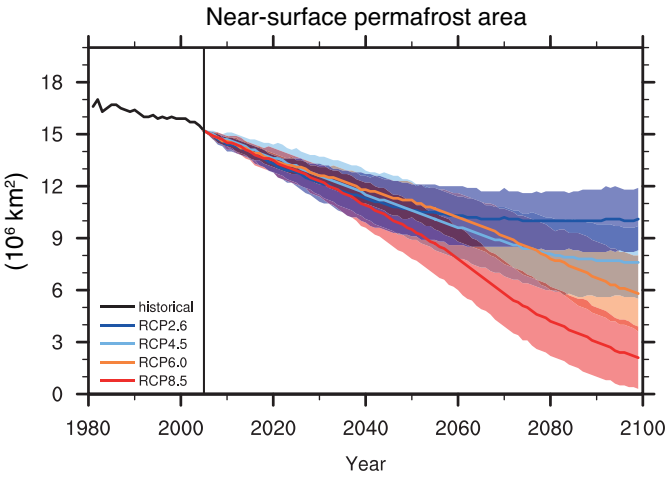

Figure 12.33 | Northern Hemisphere near-surface permafrost area, diagnosed for the available CMIP5 models by Slater and Lawrence (2013) following Nelson and Outcalt (1987) and using 20-year average bias-corrected monthly surface air temperatures and snow depths. Thick lines: multi-model average. Shading and thin lines indicate the inter-model spread (one standard deviation). The black line for the historical period is diagnosed from the average of the European Centre for Medium range Weather Forecast (ECMWF) reanalysis of the global atmosphere and surface conditions (ERA), Japanese ReAnalysis (JRA), Modern Era Retrospective-analysis for Research and Applications (MERRA) and Climate Forecast System Reanalysis and Reforecast (CFSRR) reanalyses (Slater and Lawrence, 2013). Estimated present permafrost extent is between 12 and 17 million km^2 (Zhang et al., 2000).

regions, while annual maximum SWE decreases are strong closer to the southern limit of the seasonally snow-covered area.

It is thus *very likely* (*high confidence*) that by the end of the 21st century, NH spring snow cover extent will be substantially lower than today if anthropogenic climate forcing is similar to the stronger scenarios considered here. Conversely, there is only *medium confidence* in the latitudinal pattern of annual maximum SWE changes (increase or little change in the coldest regions, stronger decrease further to the South) because annual maximum SWE is influenced by competing factors (earlier melt onset, higher solid precipitation rates in some regions).

The strong projected warming across the northern high latitudes in climate model simulations has implications for frozen ground. Recent projections of the extent of near-surface permafrost (see Glossary) degradation continue to vary widely depending on the underlying climate forcing scenario and model physics, but virtually all of them indicate substantial near-surface permafrost degradation and thaw depth deepening over much of the permafrost area (Saito et al., 2007; Lawrence et al., 2008a, 2012; Koven et al., 2011, 2013; Eliseev et al., 2013; Slater and Lawrence, 2013). Permafrost at greater depths is less directly relevant to the surface energy and water balance, and its degradation naturally occurs much more slowly (Delisle, 2007). Climate models are beginning to represent permafrost physical processes and properties more accurately (Alexeev et al., 2007; Nicolsky et al., 2007; Lawrence et al., 2008a; Rinke et al., 2008; Koven et al., 2009; Gouttevin et al., 2012), but there are large disagreements in the calculation of current frozen soil extent and active layer depth due to differences in the land model physics in the CMIP5 ensemble (Koven et al., 2013). The projected changes in permafrost are a response not only to warming, but also to changes in snow conditions because snow properties and their seasonal evolution exert significant control on soil thermal state (Zhang, 2005; Lawrence and Slater, 2010; Shkolnik et al., 2010; Koven et al., 2013). Applying the surface frost index method (Nelson and Outcalt, 1987) to coupled climate model anomalies from the CMIP5 models (Slater and Lawrence, 2013) yields a reduction of the diagnosed 2080–2099 near-surface permafrost area (continuous plus discontinuous near-surface permafrost) by 37 ± 11% (RCP2.6), 51 ± 13% (RCP4.5), 58 ± 13% (RCP6.0), and 81±12% (RCP8.5), compared to the 1986–2005 diagnosed near-surface permafrost area, with *medium confidence* in the numbers as such because of the strongly simplified soil physical processes in current-generation global climate models (Figure 12.33). The uncertainty range given here is the 1-σ inter-model dispersion. Applying directly the model output to diagnose permafrost extent and its changes over the 21st century yields similar relative changes (Koven et al., 2013). In summary, based on high agreement across CMIP5 and older model projections, fundamental process understanding, and paleoclimatic evidence (e.g., Vaks et al., 2013), it appears *virtually certain* (*high confidence*) that near-surface permafrost extent will shrink as global climate warms. However, the amplitude of the projected reductions of near-surface permafrost extent not only depends on the emission scenario and the global climate model response, but also very much on the permafrost-related soil processes taken into account in the models.

12.4.7 Changes in the Ocean

12.4.7.1 Sea Surface Temperature, Salinity and Ocean Heat Content

Projected increase of SST and heat content over the next two decades is relatively insensitive to the emissions trajectory. However, projected outcomes diverge as the 21st century progresses. When SSTs increase as a result of external forcing, the interior water masses respond to the integrated signal at the surface, which is then propagated down to greater depth (Gleckler et al., 2006; Gregory, 2010). Changes in globally averaged ocean heat content currently account for about 90% of the change in global energy inventory since 1970 (see Box 3.1). Heat is transported within the interior of the ocean by its large-scale general circulation and by smaller-scale mixing processes. Changes in transports lead to redistribution of existing heat content and can cause local cooling even though the global mean heat content is rising (Banks and Gregory, 2006; Lowe and Gregory, 2006; Xie and Vallis, 2012).

Figure 12.12 shows the multi-model mean projections of zonally averaged ocean temperature change under three emission scenarios. The differences in projected ocean temperature changes for different RCPs manifest themselves more markedly as the century progresses. The largest warming is found in the top few hundred metres of the subtropical gyres, similar to the observed pattern of ocean temperature changes (Levitus et al., 2012, see also Section 3.2). Surface warming varies considerably between the emission scenarios ranging from about 1°C (RCP2.6) to more than 3°C in RCP8.5. Mixing and advection processes gradually transfer the additional heat to deeper levels of about 2000 m at the end of the 21st century. Depending on the emission scenario, global ocean warming between 0.5°C (RCP2.6) and 1.5°C (RCP8.5) will reach a depth of about 1 km by the end of the century. The strongest warming signal is found at the surface in subtropical and tropical regions. At depth the warming is most pronounced in the Southern Ocean. From an energy point of view, for RCP4.5 by the end of the 21st century, half of the energy taken up by the ocean is in the uppermost 700 m, and 85% is in the uppermost 2000 m.

In addition to the upper-level warming, the patterns are further characterized by a slight cooling in parts of the northern mid- and high latitudes below 1000 m and a pronounced heat uptake in the deep Southern Ocean at the end of the 21st century. The cooling may be linked to the projected decrease of the strength of the AMOC (see Section 12.4.7.2; 13.4.1; Banks and Gregory, 2006).

The response of ocean temperatures to external forcing comprises mainly two time scales: a relatively fast adjustment of the ocean mixed layer and the slow response of the deep ocean (Hansen et al., 1985; Knutti et al., 2008a; Held et al., 2010). Simulations with coupled ocean–atmosphere GCMs suggest time-scales of several millennia until the deep ocean is in equilibrium with the external forcing (Stouffer, 2004; Hansen et al., 2011; Li et al., 2013a). Thus, the long time-scale of the ocean response to external forcing implies an additional commitment to warming for many centuries when GHG emissions are decreased or concentrations kept constant (see Section 12.5.2). Further assessment of ocean heat uptake and its relationship to projections of sea level rise is presented in Section 13.4.1.

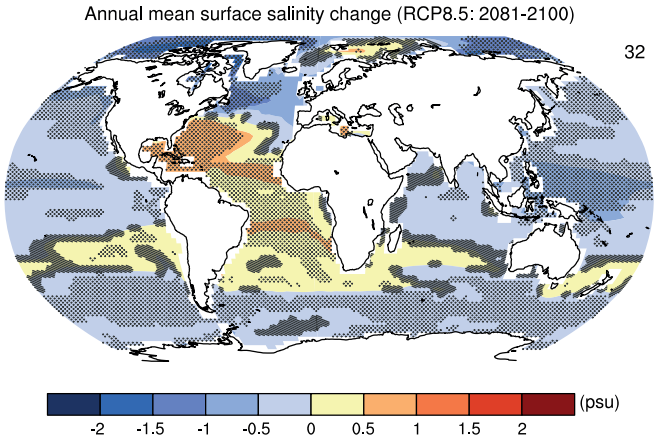

Figure 12.34 | Projected sea surface salinity differences 2081–2100 for RCP8.5 relative to 1986–2005 from CMIP5 models. Hatching indicates regions where the multi-model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi-model mean change is greater than two standard deviations of internal variability and where at least 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner.

Durack and Wijffels (2010) and Durack et al. (2012) examined trends in global sea surface salinity (SSS) changes over the period 1950–2008. Their analysis revealed strong, spatially coherent trends in SSS over much of the global ocean, with a pattern that bears striking resemblance to the climatological SSS field and is associated with an intensification of the global water cycle (see Sections 3.3.2.1, 10.4.2 and 12.4.5). The CMIP5 climate model projections available suggest that high SSS subtropical regions that are dominated by net evaporation are typically getting more saline; lower SSS regions at high latitudes are typically getting fresher. They also suggest a continuation of this trend in the Atlantic where subtropical surface waters become more saline as the century progresses (Figure 12.34) (see also Terray et al., 2012). At the same time, the North Pacific is projected to become less saline.

12.4.7.2 Atlantic Meridional Overturning

Almost all climate model projections reveal an increase of high latitude temperature and high latitude precipitation (Meehl et al., 2007b). Both of these effects tend to make the high latitude surface waters lighter and hence increase their stability. As seen in Figure 12.35, all models show a weakening of the AMOC over the course of the 21st century (see Section 12.5.5.2 for further analysis). Projected changes in the strength of the AMOC at high latitudes appear stronger in Geophysical Fluid Dynamics Laboratory (GFDL) CM2.1 when density is used as a vertical coordinate instead of depth (Zhang, 2010a). Once the RF is stabilized, the AMOC recovers, but in some models to less than its pre-industrial level. The recovery may include a significant overshoot (i.e., a weaker circulation may persist) if the anthropogenic RF is eliminated (Wu et al., 2011a). Gregory et al. (2005) found that for all eleven models

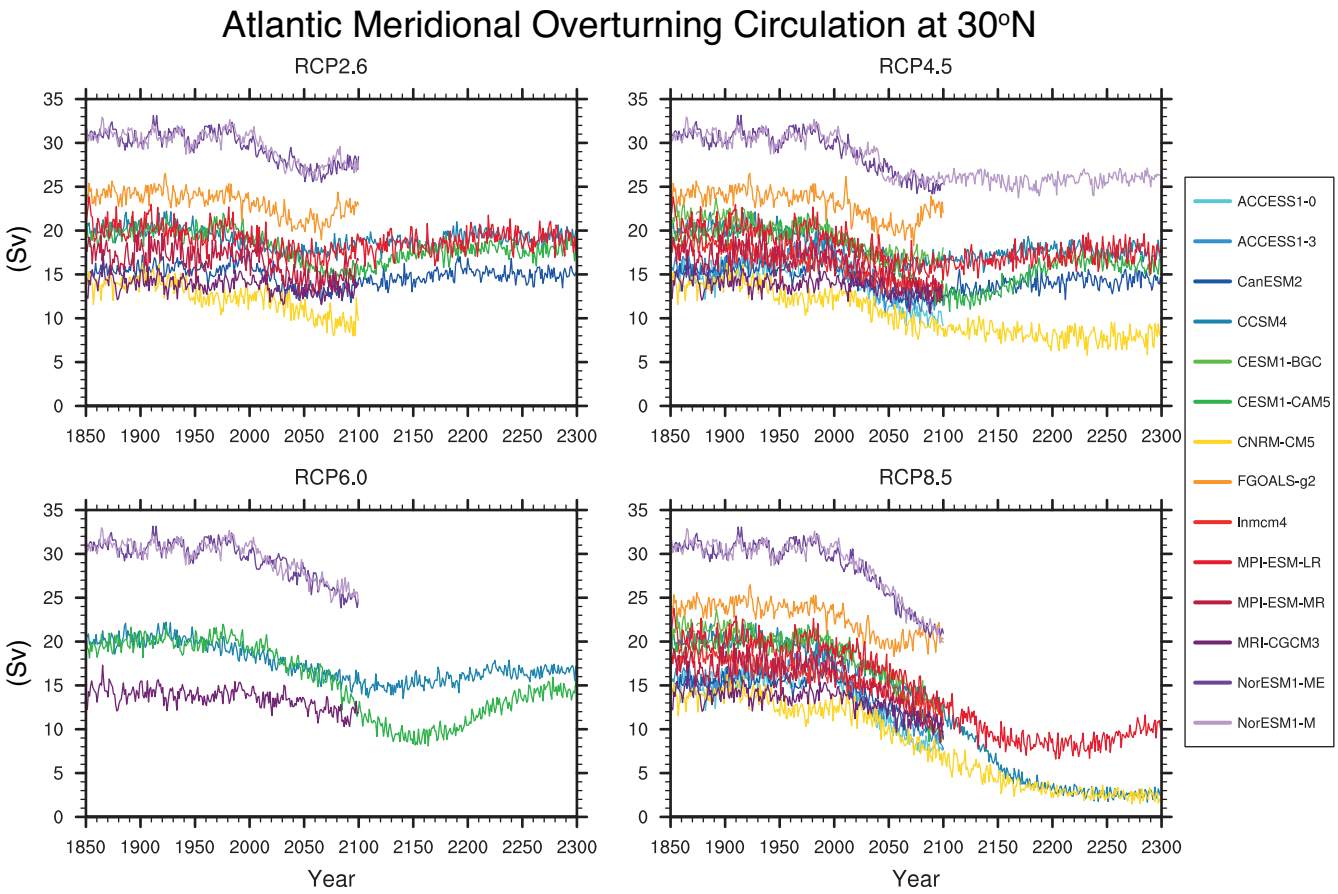

Figure 12.35 | Multi-model projections of Atlantic Meridional Overturning Circulation (AMOC) strength at 30°N from 1850 through to the end of the RCP extensions. Results are based on a small number of CMIP5 models available. Curves show results from only the first member of the submitted ensemble of experiments.

analysed (six from CMIP2/3 and five EMICs), the AMOC reduction was caused more by changes in surface heat flux than changes in surface freshwater flux. They further found that models with a stronger AMOC in their control run exhibited a larger weakening (see also Gregory and Tailleux, 2011).

Based on the assessment of the CMIP5 RCP simulations and on our understanding gleaned from analysis of CMIP3 models, observations and our understanding of physical mechanisms, it is *very likely* that the AMOC will weaken over the 21st century. Best estimates and ranges for the reduction from CMIP5 are 11% (1 to 24%) in RCP2.6 and 34% (12 to 54%) in RCP8.5. There is *low confidence* in assessing the evolution of the AMOC beyond the 21st century.

12.4.7.3 Southern Ocean

A dominant and robust feature of the CMIP3 climate projections assessed in AR4 is the weaker surface warming at the end of the 21st century in the Southern Ocean area compared to the global mean. Furthermore, the Antarctic Circumpolar Current (ACC) moves southward in most of the climate projections analysed in response to the simulated southward shift and strengthening of the SH mid-latitude westerlies (Meehl et al., 2007b).

The additional analyses of the CMIP3 model output performed since the release of AR4 confirm and refine the earlier findings. The displacement and intensification of the mid-latitude westerlies contribute to a large warming between 40°S and 60°S from the surface to mid-depths (Fyfe et al., 2007; Sen Gupta et al., 2009). Part of this warming has been attributed to the southward translation of the Southern Ocean current system (Sen Gupta et al., 2009). Moreover, the wind changes influence the surface temperature through modifications of the latent and sensible heat fluxes and force a larger northward Ekman transport of relatively cold polar surface water (Screen et al., 2010). This also leads to a stronger upwelling that brings southward and upward relatively warm and salty deep water, resulting in a subsurface salinity increase at mid-depths south of 50°S (Sen Gupta et al., 2009; Screen et al., 2010).

Overall, CMIP3 climate projections exhibit a decrease in mixed layer depth at southern mid- and high latitudes by the end of the 21st century. This feature is a consequence of the enhanced stratification resulting from surface warming and freshening (Lefebvre and Goosse, 2008; Sen Gupta et al., 2009; Capotondi et al., 2012). Despite large inter-model differences, there is a robust weakening of Antarctic Bottom Water production and its northward outflow, which is consistent with the decrease in surface density and is manifest as a warming signal close to the Antarctic margin that reaches abyssal depths (Sen Gupta et al., 2009).

In the vicinity of the Antarctic ice sheet, CMIP3 models project an average warming of ~0.5C° at depths of 200–500 m in 2091–2100 compared to 1991–2000 for the SRES A1B scenario, which has the potential to impact the mass balance of ice shelves (Yin et al., 2011). More detailed regional modelling using the SRES A1B scenario indicates that a redirection of the coastal current into the cavities underlying the Filchner-Ronne ice shelf during the second half of the 21st century might enhance the average basal melting rate there from 0.2 m yr^{-1} to almost 4 m yr^{-1} (Hellmer et al., 2012; see Section 13.4.4.2).

There are very few published analyses of CMIP5 climate projections focusing on the Southern Ocean. Meijers et al. (2012) found a wide variety of ACC responses to climate warming scenarios across CMIP5 models. Models show a high correlation between the changes in ACC strength and position, with a southward (northward) shift of the ACC core as the ACC gets stronger (weaker). No clear relationship between future changes in wind stress and ACC strength was identified, while the weakening of the ACC transport simulated at the end of the 21st century by many models was found to correlate with the strong decrease in the surface heat and freshwater fluxes in the ACC region (Meijers et al., 2012; Downes and Hogg, 2013). In agreement with the CMIP3 assessment (Sen Gupta et al., 2009), subtropical gyres generally strengthen under RCP4.5 and RCP8.5 and all expand southward, inducing a southward shift of the northern boundary of the ACC at most longitudes in the majority of CMIP5 models (Meijers et al., 2012). As in CMIP3 climate projections, an overall shallowing of the deep mixed layers that develop on the northern edge of the ACC in winter is observed, with larger shallowing simulated by models with deeper mixed layers during 1976–2005 (Sallée et al., 2013a). Sallée et al. (2013b) reported a warming of all mode, intermediate and deep water masses in the Southern Ocean. The largest temperature increase is found in mode and intermediate water layers. Consistently with CMIP3 projections (Downes et al., 2010), these water layers experience a freshening, whereas bottom water becomes slightly saltier. Finally, Sallée et al. (2013b) noted an enhanced upwelling of circumpolar deep water and an increased subduction of intermediate water that are nearly balanced by interior processes (diapycnal fluxes).

A number of studies suggest that oceanic mesoscale eddies might influence the response of the Southern Ocean circulation, meridional heat transport and deep water formation to changes in wind stress and surface buoyancy flux (Böning et al., 2008; Farneti et al., 2010; Downes et al., 2011; Farneti and Gent, 2011; Saenko et al., 2012; Spence et al., 2012). These eddies are not explicitly resolved in climate models and their role in future circulation changes still needs to be precisely quantified. Some of the CMIP5 models have output the meridional overturning due to the Eulerian mean circulation and that induced by parameterized eddies, thus providing a quantitative estimate of the role of the mesoscale circulation in a warming climate. On this basis, Downes and Hogg (2013) found that, under RCP8.5, the strengthening (weakening) of the upper (lower) Eulerian mean meridional overturning cell in the Southern Ocean is significantly correlated with the increased overlying wind stress and surface warming and is partly compensated at best by changes in eddy-induced overturning.

None of the CMIP3 and CMIP5 models include an interactive ice sheet component. When climate–ice sheet interactions are accounted for in an EMIC under a 4 × CO_2 scenario, the meltwater flux from the Antarctic ice sheet further reduces the surface density close to Antarctica and the rate of Antarctic Bottom Water formation. This ultimately results in a smaller surface warming at high southern latitudes compared to a simulation in which the freshwater flux from the melting ice sheet is not taken into account (Swingedouw et al., 2008). Nevertheless, in this study, this effect becomes significant only after more than one century.

12.4.8 Changes Associated with Carbon Cycle Feedbacks and Vegetation Cover

Climate change may affect the global biogeochemical cycles changing the magnitude of the natural sources and sinks of major GHGs. Numerous studies investigated the interactions between climate change and the carbon cycle (e.g., Friedlingstein et al., 2006), methane cycle (e.g., O'Connor et al., 2010), ozone (Cionni et al., 2011) or aerosols (e.g., Carslaw et al., 2010). Many CMIP5 ESMs now include a representation of the carbon cycle as well as atmospheric chemistry, allowing interactive projections of GHGs (mainly CO_2 and O_3) and aerosols. With such models, projections account for the imposed changes in anthropogenic emissions, but also for changes in natural sources and sinks as they respond to changes in climate and atmospheric composition. If included in ESMs, the impact on projected concentration, RF and hence on climate can be quantified. Climate-induced changes on the carbon cycle are assessed below, while changes in natural emissions of CH_4 are assessed in Chapter 6, changes in atmospheric chemistry in Chapter 11, and climate–aerosol interactions are assessed in Chapter 7.

12.4.8.1 Carbon Dioxide

As presented in Section 12.3, the CMIP5 experimental design includes, for the RCP8.5 scenario, experiments driven either by prescribed anthropogenic CO_2 emissions or concentration. The historical and 21st century emission-driven simulations allow evaluating the climate response of the Earth system when atmospheric CO_2 and the climate response are interactively being calculated by the ESMs. In such ESMs, the atmospheric CO_2 is calculated as the difference between the imposed anthropogenic emissions and the sum of land and ocean carbon uptakes. As most of these ESMs account for land use changes and their CO_2 emissions, the only external forcing is fossil fuel CO_2 emissions (along with all non-CO_2 forcings as in the C-driven RCP8.5 simulations). For a given ESM, the emission driven and concentration driven simulations would show different climate projections if the simulated atmospheric CO_2 in the emission driven run is significantly different from the one prescribed for the concentration driven runs. This would happen if the ESMs carbon cycle is different from the one simulated by MAGICC6, the model used to calculate the CMIP5 GHGs concentrations from the emissions for the four RCPs (Meinshausen et al., 2011c). When driven by CO_2 concentration, the ESMs can calculate the fossil fuel CO_2 emissions that would be compatible with the prescribed atmospheric CO_2 trajectory, allowing comparison with the set of CO_2 emissions initially estimated by the IAMs (Arora et al., 2011; Jones et al., 2013) (see Section 6.4.3, Box 6.4).

Figure 12.36 shows the simulated atmospheric CO_2 and global average surface air temperature warming (relative to the 1986–2005 reference period) for the RCP8.5 emission driven simulations from the CMIP5 ESMs, compared to the concentration driven simulations from the same models. Most (seven out of eleven) of the models estimate a larger CO_2 concentration than the prescribed one. By 2100, the multi-model average CO_2 concentration is 985 ± 97 ppm (full range 794 to 1142 ppm), while the CO_2 concentration prescribed for the RCP8.5 is 936 ppm. Figure 12.36 also shows the range of atmospheric CO_2 projections when the MAGICC6 model, used to provide the RCP concentrations, is tuned to emulate combinations of climate sensitivity uncertainty taken from 19 CMIP3 models and carbon cycle feedbacks uncertainty taken from 10 C^{4}MIP models, generating 190 model simulations (Meinshausen et al., 2011c; Meinshausen et al., 2011b). The emulation of the CMIP3/C^{4}MIP models shows for the RCP8.5, a range of simulated CO_2 concentrations of 794 to 1149 ppm (90% confidence level), extremely similar to what is obtained with the CMIP5 ESMs, with atmospheric concentration as high as 1150 ppm by 2100, that is, more than 200 ppm above the prescribed CO_2 concentration.

Global warming simulated by the E-driven runs show higher upper ends than when atmospheric CO_2 concentration is prescribed. For the models assessed here, the global surface temperature change (2081–2100 average relative to 1986–2005 average) ranges between 2.6°C and 4.7°C, with a multi-model average of 3.7°C ± 0.7°C for the concentration driven simulations, while the emission driven simulations give a range of 2.5°C to 5.6°C, with a multi-model average of 3.9°C ± 0.9°C, that is, 5% larger than for the concentration driven runs. The models that simulate the largest CO_2 concentration by 2100 have the largest warming amplification in the emission driven simulations, with an additional warming of more than 0.5°C.

The uncertainty on the carbon cycle has been shown to be of comparable magnitude to the uncertainty arising from physical climate processes (Gregory et al., 2009). Huntingford et al. (2009) used a simple model to characterize the relative role of carbon cycle and climate sensitivity uncertainties in contributing to the range of future temperature changes, concluding that the range of carbon cycle processes represent about 40% of the physical feedbacks. Perturbed parameter ensembles systematically explore land carbon cycle parameter uncertainty and illustrate that a wide range of carbon cycle responses are consistent with the same underlying model structures and plausible parameter ranges (Booth et al., 2012; Lambert et al., 2012). Figure 12.37 shows how the comparable range of future climate change (SRES A1B) arises from parametric uncertainty in land carbon cycle and atmospheric feedbacks. The same ensemble shows that the range of atmospheric CO_2 in the land carbon cycle ensemble is wider than the full SRES concentration range (B1 to A1FI scenario).

The CMIP5 ESMs described above do not include the positive feedback arising from the carbon release from high latitudes permafrost thawing under a warming scenario, which could further increase the atmospheric CO_2 concentration and the warming. Two recent studies investigated the climate–permafrost feedback from simulations with models of intermediate complexity (EMICs) that accounts for a permafrost carbon module (MacDougall et al., 2012; Schneider von Deimling et al., 2012). Burke et al. (2012) also estimated carbon loss from permafrost, from a diagnostic of the present-day permafrost carbon store and future soil warming as simulated by CMIP5 models. However, this last study did not quantify the effect on global temperature. Each of these studies found that the range of additional warming due to the permafrost carbon loss is quite large, because of uncertainties in future high latitude soil warming, amount of carbon stored in permafrost soils, vulnerability of freshly thawed organic material, the proportion of soil carbon that might be emitted as carbon dioxide via aerobic decomposition or as methane via anaerobic decomposition (Schneider von Deimling et al., 2012). For the RCP8.5, the additional warming from permafrost ranges between 0.04°C and 0.69°C by 2100 although

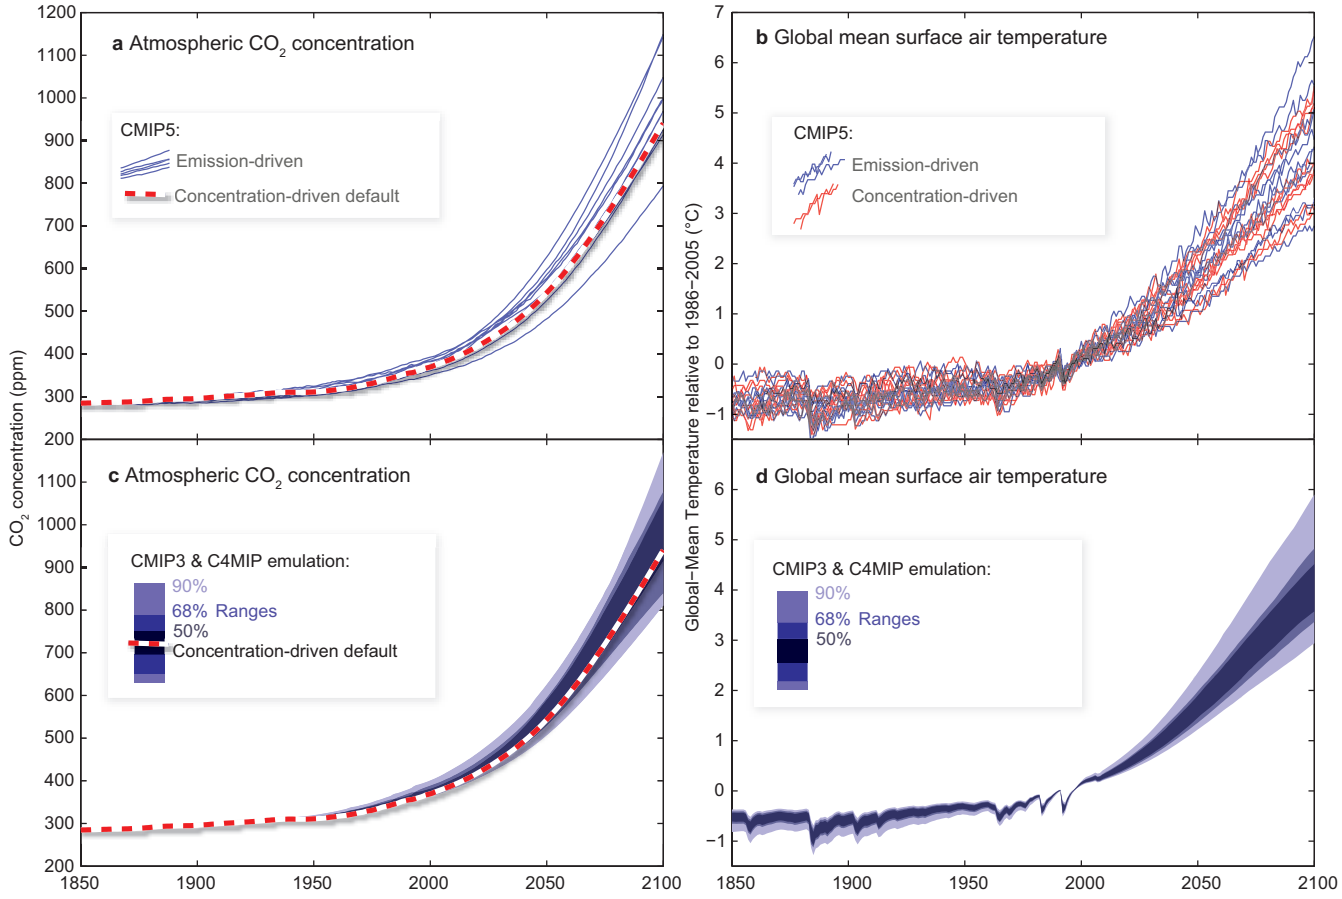

Figure 12.36 | Simulated changes in (a) atmospheric CO_2 concentration and (b) global averaged surface temperature (°C) as calculated by the CMIP5 Earth System Models (ESMs) for the RCP8.5 scenario when CO_2 emissions are prescribed to the ESMs as external forcing (blue). Also shown (b, in red) is the simulated warming from the same ESMs when directly forced by atmospheric CO_2 concentration (a, red white line). Panels (c) and (d) show the range of CO_2 concentrations and global average surface temperature change simulated by the Model for the Assessment of Greenhouse Gas-Induced Climate Change 6 (MAGICC6) simple climate model when emulating the CMIP3 models climate sensitivity range and the Coupled Climate Carbon Cycle Model Intercomparison Project (C^4MIP) models carbon cycle feedbacks. The default line in (c) is identical to the one in (a).

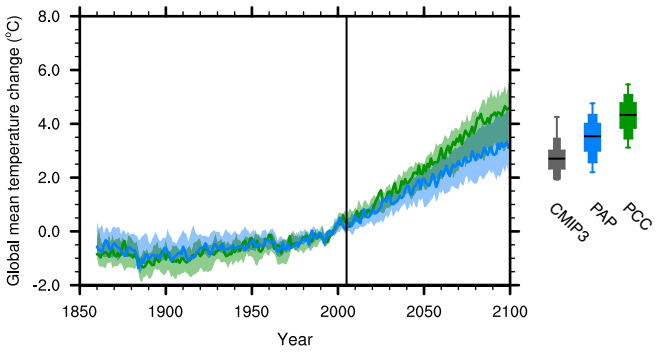

Figure 12.37 | Uncertainty in global mean temperature from Met Office Hadley Centre climate prediction model 3 (HadCM3) results exploring atmospheric physics and terrestrial carbon cycle parameter perturbations under the SRES A1B scenario (Murphy et al., 2004; Booth et al., 2012). Relative uncertainties in the Perturbed Carbon Cycle (PCC, green plume) and Perturbed Atmospheric Processes (PAP, blue plume) on global mean anomalies of temperature (relative to the 1986–2005 period). The standard simulations from the two ensembles, HadCM3 (blue solid) and HadCM3C (green solid) are also shown. Three bars are shown on the right illustrating the 2100 temperature anomalies associated with the CMIP3/AR4 ensemble (black) the PAP ensemble (blue) and PCC ensemble (green). The ranges indicate the full range, 10th to 90th, 25th to 75th and 50th percentiles.

there is *medium confidence* in these numbers as are the ones on the amount of carbon released (see Section 12.5.5.4) (MacDougall et al., 2012; Schneider von Deimling et al., 2012).

12.4.8.2 Changes in Vegetation Cover

Vegetation cover can also be affected by climate change, with forest cover potentially being decreasing (e.g., in the tropics) or increasing (e.g., in high latitudes). In particular, the Amazon forest has been the subject of several studies, generally agreeing that future climate change would increase the risk tropical Amazon forest being replaced by seasonal forest or even savannah (Huntingford et al., 2008; Jones et al., 2009; Malhi et al., 2009). Increase in atmospheric CO_2 would partly reduce such risk, through increase in water efficiency under elevated CO_2 (Lapola et al., 2009; Malhi et al., 2009). Recent multi-model estimates based on different CMIP3 climate scenarios and different dynamic global vegetation models predict a moderate risk of tropical forest reduction in South America and even lower risk for African and Asian tropical forests (see also Section 12.5.5.6) (Gumpenberger et al., 2010; Huntingford et al., 2013).

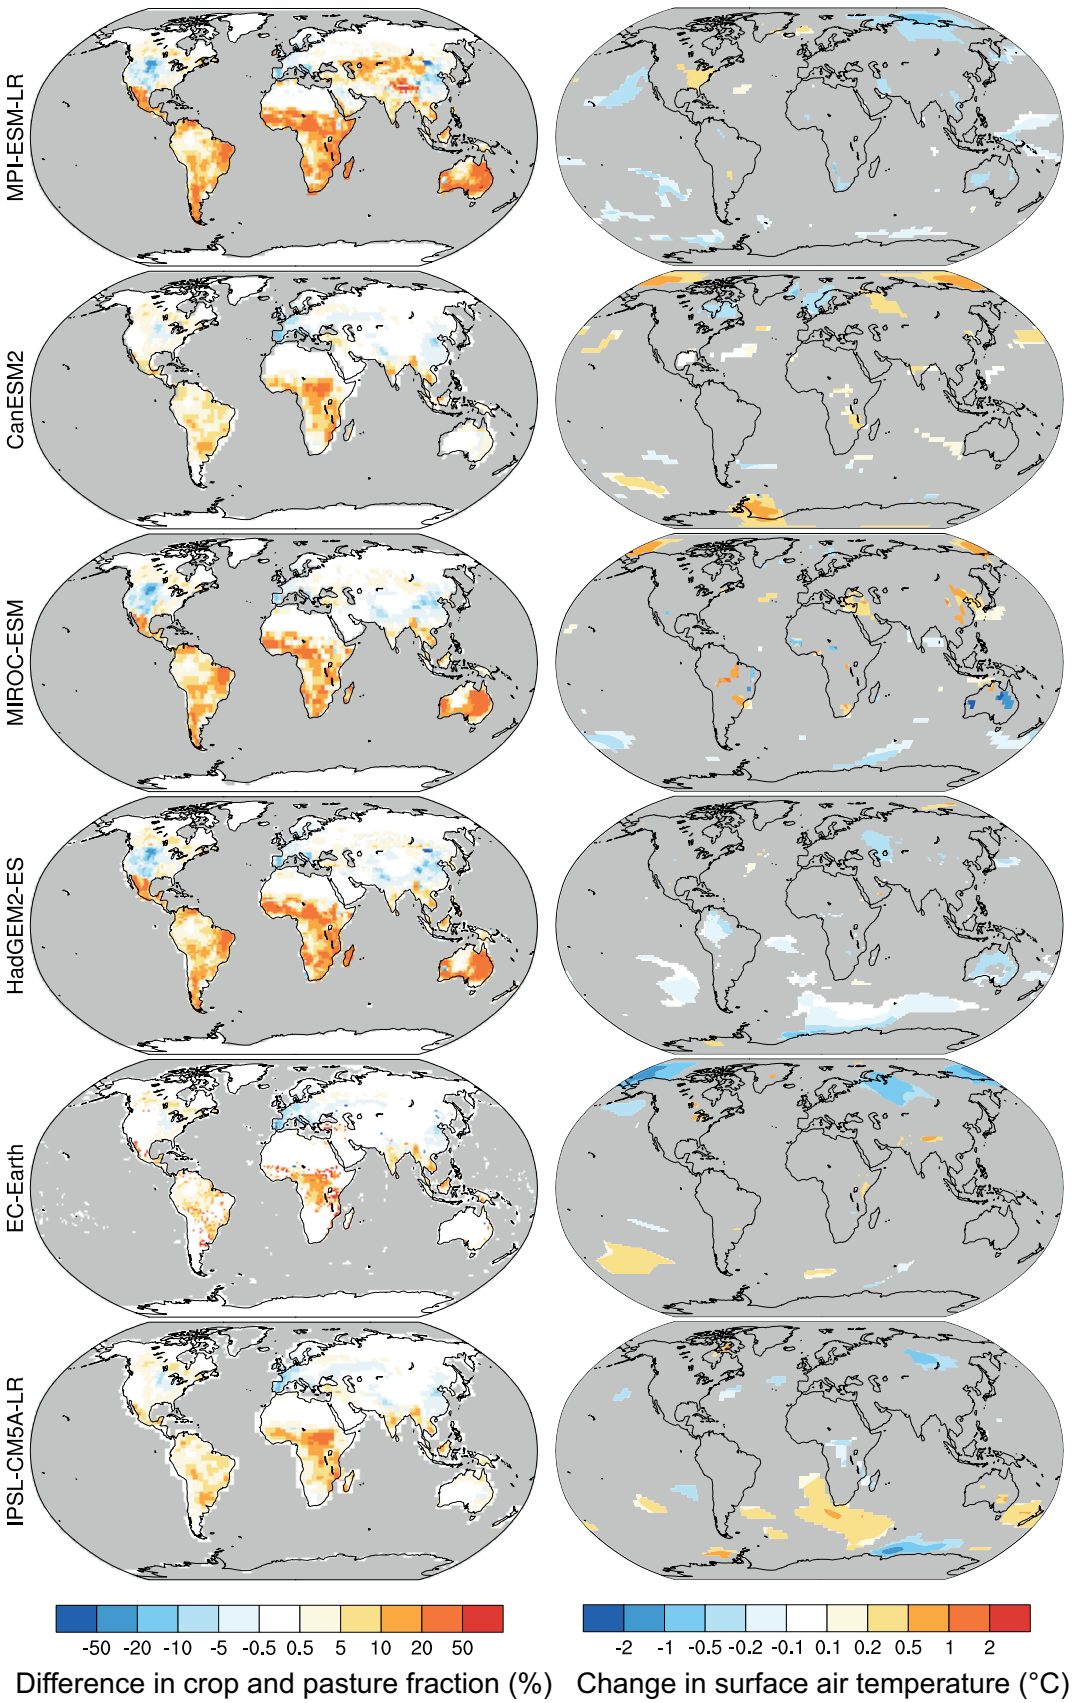

Figure 12.38 | Impact of land use change on surface temperature. LUCID-CMIP5 experiments where six ESMs were forced either with or without land use change beyond 2005 under the RCP8.5 scenario. Left maps of changes in total crop and pasture fraction (%) in the RCP8.5 simulations between 2006 and 2100 as implemented in each ESM. Right maps show the differences in surface air temperature (averaged over the 2071–2100 period) between the simulations with and without land use change beyond 2005. Only statistically significant changes ($p < 0.05$) are shown.

ESMs simulations with interactive vegetation confirmed known biophysical feedback associated with large-scale changes in vegetation. In the northern high latitudes, warming-induced vegetation expansion reduces surface albedo, enhancing the warming over these regions (Falloon et al., 2012; Port et al., 2012), with potentially larger amplification due to ocean and sea ice response (Swann et al., 2010). Over tropical forest, reduction of forest coverage would reduce evapotranspiration, also leading to a regional warming (Falloon et al., 2012; Port et al., 2012).

CMIP5 ESMs also include human induced land cover changes (deforestation, reforestation) affecting the climate system through changes in land surface physical properties (Hurtt et al., 2011). Future changes in land cover will have an impact on the climate system through biophysical and biogeochemical processes (e.g., Pongratz et al., 2010). Biophysical processes include changes in surface albedo and changes in partitioning between latent and sensible heat, while biogeochemical feedbacks essentially include change in CO_2 sources and sinks but could potentially also include changes in N_2O or CH_4 emissions. The biophysical response to future land cover changes has been investigated within the SRES scenarios. Using the SRES A2 2100 land cover, Davin et al. (2007) simulated a global cooling of 0.14 K relatively to a simulation with present-day land cover, the cooling being largely driven by change in albedo. Regional analyses have been performed in order to quantify the biophysical impact of biofuels plantation generally finding a local to regional cooling when annual crops are replaced by bioenergy crops, such as sugar cane (Georgescu et al., 2011; Loarie et al., 2011). However, some energy crops require nitrogen inputs for their production, leading inevitably to nitrous oxide (N_2O) emissions, potentially reducing the direct cooling effect and the benefit of biofuels as an alternative to fossil fuel emissions. Such emission estimates are still uncertain, varying strongly for different crops, management methods, soil types and reference systems (St. Clair et al., 2008; Smeets et al., 2009).

In the context of the Land-Use and Climate, IDentification of robust impacts (LUCID) project (Pitman et al., 2009) ESMs performed additional CMIP5 simulations in order to separate the biophysical from the biogeochemical effects of land use changes in the RCP scenarios. The LUCID–CMIP5 experiments were designed to complement RCP8.5 and RCP2.6 simulations of CMIP5, both of which showing an intensification of land use change over the 21st century. The LUCID–CMIP5 analysis was focussed on a difference in climate and land-atmosphere fluxes between the average of ensemble of simulations with and without land use changes by the end of 21st century (Brovkin et al., 2013). Due to different interpretation of land use classes, areas of crops and pastures were specific for each ESM (Figure 12.38, left). On the global scale, simulated biophysical effects of land use changes projected in the CMIP5 experiments with prescribed CO_2 concentrations were not significant. However, these effects were significant for regions with land use changes >10%. Only three out of six participating models, CanESM2, HadGEM2-ES and MIROC-ESM, reveal statistically significant changes in regional mean annual mean surface air temperature for the RCP8.5 scenario (Figure 12.38, right). However, there is *low confidence* on the overall effect as there is no agreement among the models on the sign of the global average temperature change due to the biophysical effects of land use changes (Brovkin et al., 2013). Changes in land surface albedo, available energy, latent and sensible heat fluxes were relatively small but significant in most of ESMs for regions with substantial land use changes. The scale of climatic effects reflects a small magnitude of land use changes in both the RCP2.6 and 8.5 scenarios and their limitation mainly to the tropical and subtropical regions where differences between biophysical effects of forests and grasslands are less pronounced than in mid- and high latitudes. LUCID-CMIP5 did not perform similar simulations for the RCP4.5 or RCP6.0 scenarios. As these two scenarios show a global decrease of land use area, one might expect their climatic impact to be different from the one seen in the RC2.6 and RCP8.5.

12.4.9 Consistency and Main Differences Between Coupled Model Intercomparison Project Phase 3/ Coupled Model Intercomparison Project Phase 5 and Special Report on Emission Scenarios/ Representative Concentration Pathways

In the experiments collected under CMIP5, both models and scenario have changed with respect to CMIP3 making a comparison with earlier results and the scientific literature they generated (on which some of this chapter's content is still based) complex. The set of models used in AR4 (the CMIP3 models) have been superseded by the new CMIP5 models (Table 12.1; Chapter 9) and the SRES scenarios have been replaced by four RCPs (Section 12.3.1). In addition, the baseline period used to compute anomalies has advanced 6 years, from 1980–1999 to 1986–2005.

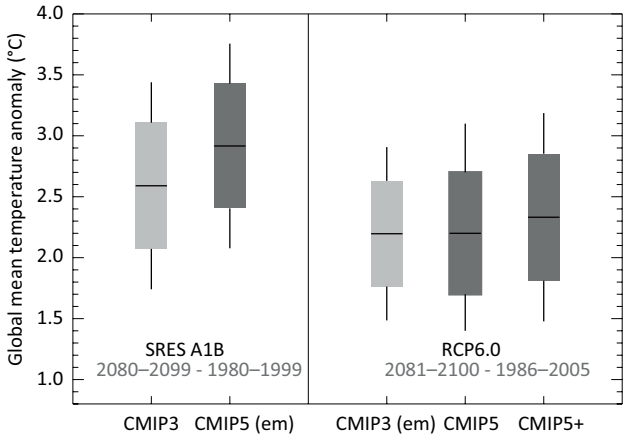

Figure 12.39 | Global mean temperature anomalies at the end of the 21st century from General Circulation Model (GCM) experiments and emulators comparing CMIP3/CMIP5 responses under SRES A1B and RCP6.0. The boxes and whiskers indicate the 5th percentile, mean value – 1 standard deviation, mean, mean value + 1 standard deviation and 95th percentile of the distributions. The first box-and-whiskers on the left is computed directly from the CMIP3 ensemble and corresponds to the numbers quoted in AR4. The emulated SRES A1B projections (second from left) of CMIP5 are obtained by the method of Good et al. (2011a) and are calculated for the period 2080-2099 expressed with respect to the AR4 baseline period of 1980–1999. Because of the method, the subset of CMIP5 that are emulated are restricted to those with pre-industrial control, abrupt 4 × CO_2, historical, RCP4.5 and RCP8.5 simulations. The emulated RCP6.0 projections of CMIP3 (third from left, see also Figure 12.8) are from Knutti and Sedláček (2013) obtained using the method of Meinshausen et al. (2011b; 2011c) and are calculated for the slightly different future period 2081–2100 to be consistent with the rest of this chapter, and are expressed with respect to the AR5 baseline period of 1986–2005. The box-and-whiskers fourth from the left are a graphical representation of the numbers shown in Table 12.2. The final box-and-whiskers on the right is a combination of CMIP5 model output and emulation of CMIP5 RCP6.0 numbers for those models that did not run RCP6.0.

It would be extremely costly computationally to rerun the full CMIP3 ensemble under the new RCPs and/or the full CMIP5 ensemble under the old SRES scenarios in order to separate model and scenario effects. In the absence of a direct comparison, we rely on simplified modelling frameworks to emulate CMIP3/5 SRES/RCP model behaviour and compare them. Figure 12.39 shows an emulation of the global mean temperature response at the end of the 21st century that one would expect from the CMIP5 models if they were run under SRES A1B. In this case, anomalies are computed with respect to 1980–1999 for direct comparison with the values reported in AR4 (Meehl et al., 2007b) which used that baseline. The method used to emulate the SRES A1B response of the CMIP5 is documented by Good et al. (2011a; 2013). Ensemble-mean A1B RF was computed from CMIP3 projections using the Forster and Taylor (2006) method, scaled to ensure consistency with the forcing required by the method. The simple model is only used to predict the temperature difference between A1B and RCP8.5, and between A1B and RCP4.5 separately for each model. These differences are then added to CMIP5 GCM simulations of RCP8.5 and RCP4.5 respectively, and averaged to give a single A1B estimate. The emulated CMIP5 SRES A1B results show a slightly larger mean response than the actual CMIP3 models, with a similar spread (±1 standard deviation is used in this case). The main reason for this is the slightly larger mean transient climate response (TCR) in the subset of CMIP5 models available in comparison with the AR4 CMIP3 models. An alternative emulation is presented by Knutti and Sedláček (2013) who use the simplified MAGICC models with parameters chosen to emulate the response of the CMIP3 models to RCP6.0 forcing, with anomalies expressed with respect to the 1986–2005 baseline period (Figure 12.39). They too find a larger mean response in the CMIP5 case but also a larger spread (±1 standard deviation) in CMIP5. Uncertainties in the different approaches to emulating climate model simulations, for example estimating the non-GHG RF, and the small sample sizes of CMIP3 and CMIP5 make it difficult to draw conclusions on the statistical significance of the differences displayed in Figure 12.39, but the same uncertainties lead us to conclude that on the basis of these analyses there appears to be no fundamental difference between the behaviour of the CMIP5 ensemble, in comparison with CMIP3.

Meinshausen et al. (2011a; 2011b) tuned MAGICC6 to emulate 19 GCMs from CMIP3. The results are temperature projections and their uncertainties (based on the empirical distribution of the ensemble) under each of the RCPs, extended to year 2500 (under constant emissions for the lowest RCP and constant concentrations for the remaining three). In the same paper, an ensemble produced by combining carbon cycle parameter calibration to nine C⁴MIP models with the 19 CMIP3 model parameter calibrations is also used to estimate the emissions implied by the various concentration pathways, had the CMIP3 models included a carbon cycle component. Rogelj et al. (2012) used the same tool but performed a fully probabilistic analysis of the SRES and RCP scenarios using a parameter space that is consistent with

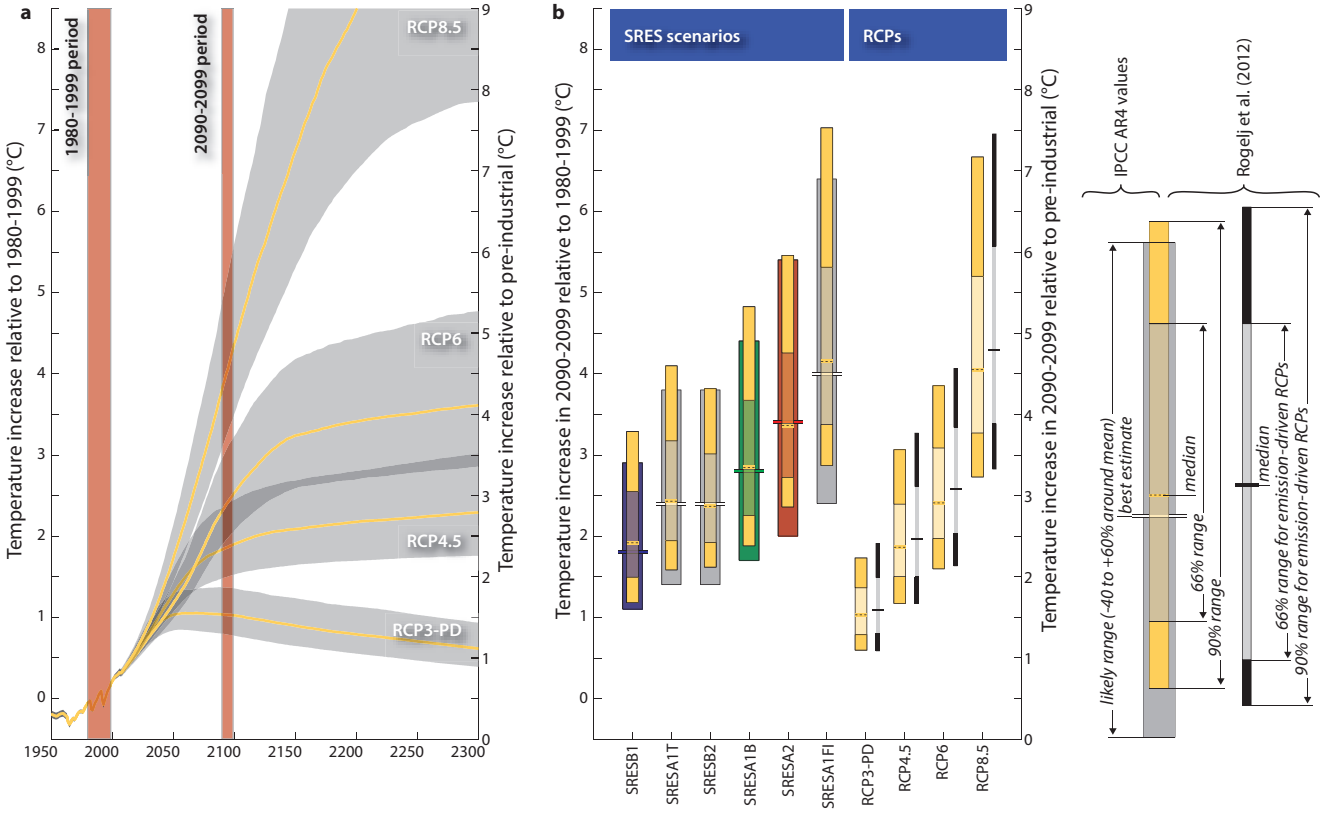

Figure 12.40 | Temperature projections for SRES scenarios and the RCPs. (a) Time-evolving temperature distributions (66% range) for the four RCP scenarios computed with the ECS distribution from Rogelj et al. (2012) and a model setup representing closely the carbon-cycle and climate system uncertainty estimates of the AR4 (grey areas). Median paths are drawn in yellow. Red shaded areas indicate time periods referred to in panel b. (b) Ranges of estimated average temperature increase between 2090 and 2099 for SRES scenarios and the RCPs respectively. Note that results are given both relative to 1980–1999 (left scale) and relative to pre-industrial (right scale). Yellow ranges indicate results obtained by Rogelj et al. (2012). Colour-coding of AR4 ranges is chosen to be consistent with AR4 (Meehl et al., 2007b). RCP2.6 is labelled as RCP3-PD here.

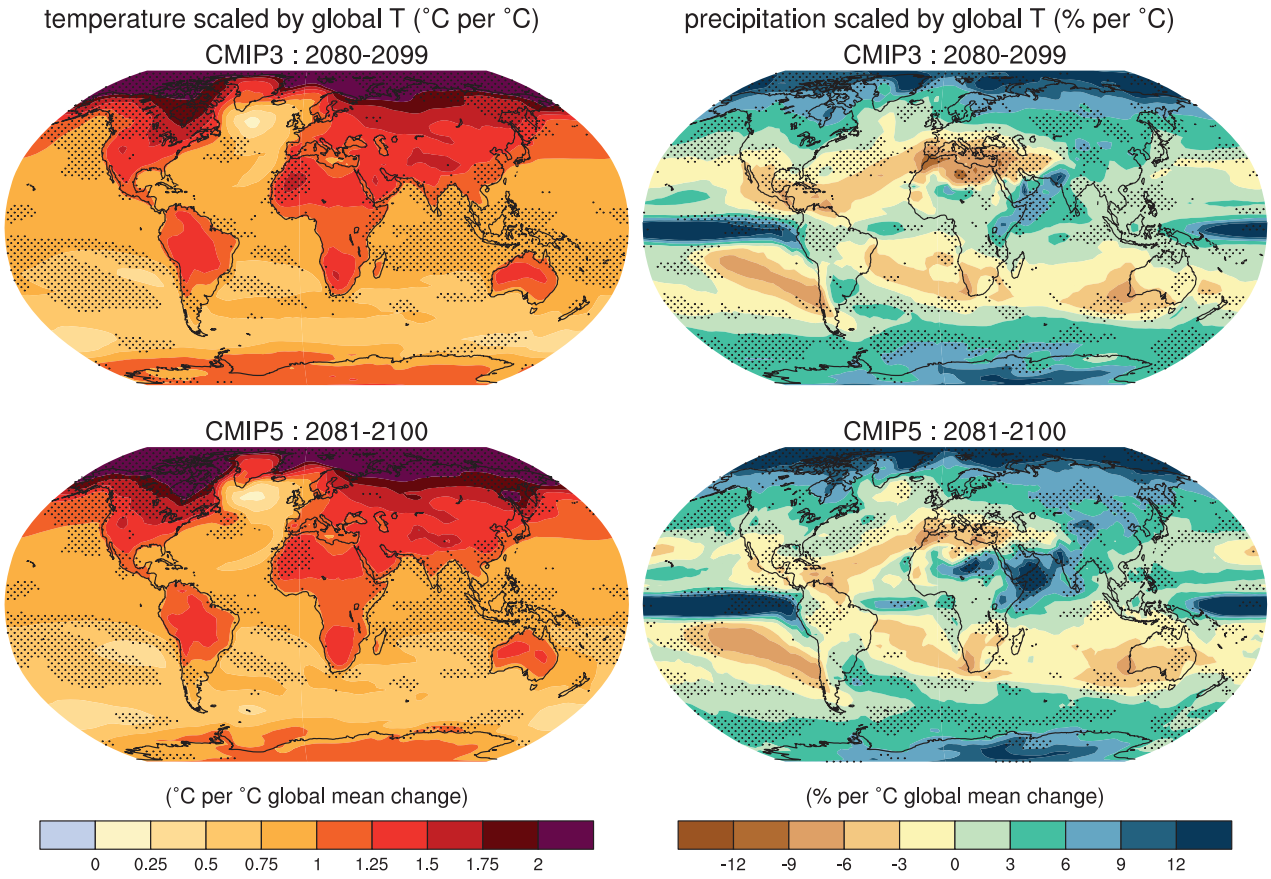

Figure 12.41 | Patterns of temperature (left column) and percent precipitation change (right column) for the CMIP3 models average (first row) and CMIP5 models average (second row), scaled by the corresponding global average temperature changes. The patterns are computed in both cases by taking the difference between the averages over the last 20 years of the 21st century experiments (2080–2099 for CMIP3 and 2081–2100 for CMIP5) and the last twenty years of the historic experiments (1980–1999 for CMIP3, 1986–2005 for CMIP5) and rescaling each difference by the corresponding change in global average temperature. This is done first for each individual model, and then the results are averaged across models. For the CMIP5 patterns, the RCP2.6 simulation of the FIO-ESM model was excluded because it did not show any warming by the end of the 21st century, thus not complying with the method requirement that the pattern be estimated at a time when the temperature change signal from CO_2 increase has emerged. Stippling indicates a measure of significance of the difference between the two corresponding patterns obtained by a bootstrap exercise. Two subsets of the pooled set of CMIP3 and CMIP5 ensemble members of the same size as the original ensembles, but without distinguishing CMIP3 from CMIP5 members, were randomly sampled 500 times. For each random sample we compute the corresponding patterns and their difference, then the true difference is compared, grid-point by grid-point, to the distribution of the bootstrapped differences, and only grid-points at which the value of the difference falls in the tails of the bootstrapped distribution (less than the 2.5 percentiles or the 97.5 percentiles) are stippled.

CMIP3/C^{4}MIP but a more general uncertainty characterization for key quantities like equilibrium climate sensitivity, similarly to the approach utilized by Meinshausen et al. (2009). Observational or other historical constraints are also used in this study and the analysis is consistent with the overall assessment of sources and ranges of uncertainties for relevant quantities (equilibrium climate sensitivity above all) from AR4 (Meehl et al., 2007b , Box 10.2). Figure 12.40 summarizes results of this probabilistic comparison for global temperature. The RCPs span a large range of stabilization, mitigation and non-mitigation pathways and the resulting range of temperature changes are larger than those produced under SRES scenarios, which do not consider mitigation options. The SRES results span an interval between just above 1.0°C and 6.5°C when considering the respective *likely* ranges of all scenarios, including B1 as the lowest and A1FI as the highest. Emissions under RCP8.5 are highest and the resulting temperature changes *likely* range from 4.0°C to 6.1°C by 2100. The lowest RCP2.6 assumes significant mitigation and the global temperature change *likely* remains below 2°C.

Similar temperature change projections by the end of the 21st century are obtained under RCP8.5 and SRES A1FI, RCP6 and SRES B2 and RCP4.5 and SRES B1. There remain large differences though in the transient trajectories, with rates of change slower or faster for the different pairs. These differences can be traced back to the interplay of the (negative) short-term effect of sulphate aerosols and the (positive) effect of long-lived GHGs. Impact studies may be sensitive to the differences in these temporal profiles so care should be taken in approximating SRES with RCPs and vice versa.

While simple models can separate the effect of the scenarios and the model response, no studies are currently available that allow an attribution of the CMIP3-CMIP5 differences to changes in the transient climate response, the carbon cycle, and the inclusion of new processes (chemistry, land surface, vegetation). The fact that these sets of CMIP3 and CMIP5 experiments do not include emission-driven runs would suggest that differences in the representation of the carbon cycle are very unlikely to explain differences in the simulations, since the only

effect of changes in the carbon cycle representation would affect the land surface, and thus would have only a minor effect on the climate response at the global scale.

Figure 12.41 shows a comparison of the patterns of warming and precipitation change from CMIP3 (using 23 models and three SRES scenarios) and CMIP5 (using 46 models and four RCPs), utilizing the pattern scaling methodology (Section 12.4.2). The geographic patterns of mean change are very similar across the two ensembles of models, with pattern correlations of 0.98 for temperature and 0.90 for precipitation changes. However there exist significant differences in the absolute values of the patterns, if not in their geographic shapes. A simple bootstrapping exercise that pooled together all models and scenarios and resampled 500 times the same numbers of models/scenarios divided into two groups, but without distinguishing CMIP3 from CMIP5 (and thus SRES from RCPs) allows to compute a measure of significance of the actual differences in the patterns. Stippling in Figure 12.41 marks the large regions where the difference is significant for temperature and precipitation patterns. The temperature pattern from CMIP5 shows significantly larger warming per degree Celsius of global mean temperature change in the NH and less warming per degree Celsius in the SH compared to the corresponding pattern from CMIP3. For precipitation patterns, CMIP5 shows significantly larger increases per degree Celsius in the NH and significantly larger decreases per degree Celsius in the SH compared to CMIP3. Even in this case we do not have studies that allow tracing the source of these differences to specific changes in models' configurations, processes represented or scenarios run.

Knutti and Sedláček (2013) attempt to identify or rule out at least some of these sources. Differences in model projections spread or its counterpart, robustness, between CMIP3 and CMIP5 are discussed, and it is shown that by comparing the behaviour of only a subset of 11 models, contributed to the two CMIPs by the same group of institutions, the robustness of CMIP5 versus that of CMIP3 actually decreases slightly. This would suggest that the enhanced robustness of CMIP5 is not clearly attributable to advances in modelling, and may be a result of the fact that the CMIP5 ensemble contains different versions of the same model that are counted as independent in this measure of robustness.

A comparison of CMIP3 and CMIP5 results for extreme indices is provided in Sections 12.4.3.3 and Figure 12.13 for temperature extremes, and Section 12.4.5.5 and Figure 12.26 for extremes in the water cycle.

12.5 Climate Change Beyond 2100, Commitment, Stabilization and Irreversibility

This section discusses the long term (century to millennia) climate change based on the RCP scenario extensions and idealized scenarios, the commitment from current atmospheric composition and from past emissions, the concept of cumulative carbon and the resulting constraints on emissions for various temperature targets. The term irreversibility is used in various ways in the literature. This report defines a perturbed state as irreversible on a given time scale if the recovery time scale from this state due to natural processes is significantly longer than the time it takes for the system to reach this perturbed state (see Glossary), for example, the climate change resulting from the long residence time of a CO_2 perturbation in the atmosphere. These results are discussed in Sections 12.5.2 to 12.5.4. Aspects of irreversibility in the context of abrupt change, multiple steady states and hysteresis are discussed in Section 12.5.5 and in Chapter 13 for ice sheets and sea level rise.

12.5.1 Representative Concentration Pathway Extensions

The CMIP5 intercomparison project includes simulations extending the four RCP scenarios to the year 2300 (see Section 12.3.1). This allows exploring the longer-term climate response to idealized GHG and aerosols forcings (Meinshausen et al., 2011c). Continuing GHG emissions beyond 2100 as in the RCP8.5 extension induces a total RF above 12 W m^{-2} by 2300, while sustaining negative emissions beyond 2100, as in the RCP2.6 extension, induces a total RF below 2 W m^{-2} by 2300. The projected warming for 2281–2300, relative to 1986–2005, is 0.6°C (range 0.0°C to 1.2°C) for RCP2.6, 2.5°C (range 1.5°C to 3.5°C) for RCP4.5, and 7.8°C (range 3.0°C to 12.6°C) for RCP8.5 (*medium confidence*, based on a limited number of CMIP5 simulations) (Figures 12.3 and 12.5, Table 12.2).

EMICs simulations have been performed following the same CMIP5 protocol for the historical simulation and RCP scenarios extended to 2300 (Zickfeld et al., 2013). These scenarios have been prolonged beyond 2300 to investigate longer-term commitment and irreversibility (see below). Up to 2300, projected warming and the reduction of the AMOC as simulated by the EMICs are similar to those simulated by the CMIP5 ESMs (Figures 12.5 and 12.42).

12.5.2 Climate Change Commitment

Climate change commitment, the fact that the climate will change further after the forcing or emissions have been eliminated or held constant, has attracted increased attention by scientists and policymakers shortly before the completion of IPCC AR4 (Hansen et al., 2005a; Meehl et al., 2005b, 2006; Wigley, 2005) (see also AR4 Section 10.7.1). However, the argument that the surface response would lag the RF due to the large thermal reservoir of the ocean in fact goes back much longer (Bryan et al., 1982; Hansen et al., 1984, 1985; Siegenthaler and Oeschger, 1984; Schlesinger, 1986; Mitchell et al., 2000; Wetherald et al., 2001). The discussion in this section is framed largely in terms of temperature change, but other changes in the climate system (e.g., precipitation) are closely related to changes in temperature (see Sections 12.4.1.1 and 12.4.2). A summary of how past emissions relate to future warming is also given in FAQ 12.3.

The Earth system has multiple response time scales related to different thermal reservoirs (see also Section 12.5.3). For a step change in forcing (instantaneous increase in the magnitude of the forcing and constant forcing after that), a large fraction of the total of the surface temperature response will be realized within years to a few decades (Brasseur and Roeckner, 2005; Knutti et al., 2008a; Murphy et al., 2009; Hansen et al., 2011). The remaining response, realized over centuries, is controlled by the slow mixing of the energy perturbation into the ocean (Stouffer, 2004). The response time scale depends on the amount of ocean mixing

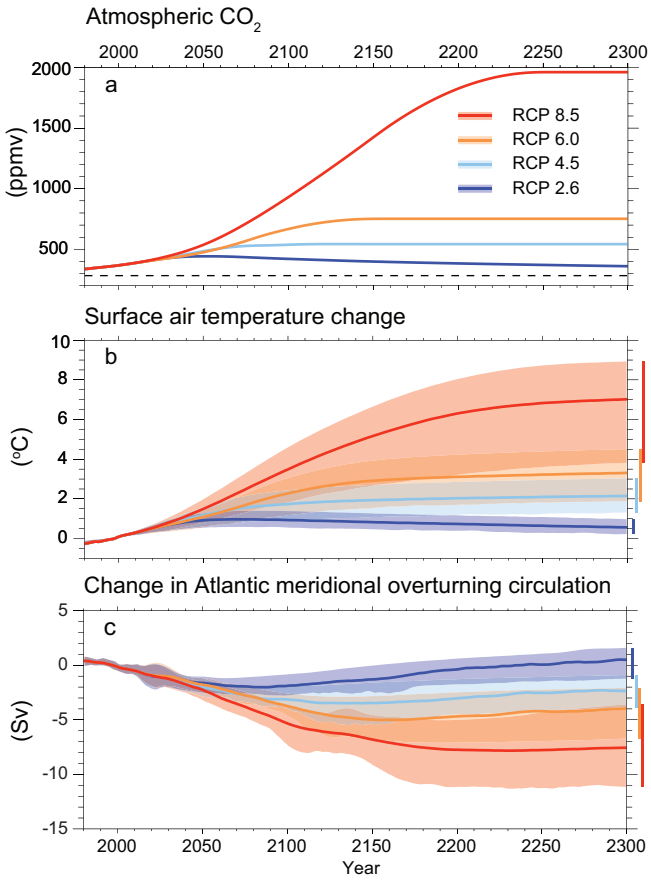

Figure 12.42 | (a) Atmospheric CO_2, (b) projected global mean surface temperature change and (c) projected change in the Atlantic meridional overturning circulation, as simulated by EMICs for the four RCPs up to 2300 (Zickfeld et al., 2013). A 10-year smoothing was applied. Shadings and bars denote the minimum to maximum range. The dashed line on (a) indicates the pre-industrial CO_2 concentration.

and the strength of climate feedbacks, and is longer for higher climate sensitivity (Hansen et al., 1985; Knutti et al., 2005). The transient climate response is therefore smaller than the equilibrium response, in particular for high climate sensitivities. This can also be interpreted as the ocean heat uptake being a negative feedback (Dufresne and Bony, 2008; Gregory and Forster, 2008). Delayed responses can also occur due to processes other than ocean warming, for example, vegetation change (Jones et al., 2009) or ice sheet melt that continues long after the forcing has been stabilized (see Section 12.5.3).

Several forms of commitment are often discussed in the literature. The most common is the 'constant composition commitment', the warming that would occur after stabilizing all radiative constituents at a given year (for example year 2000) levels. For year 2000 commitment, AOGCMs estimated a most likely value of about 0.6°C for 2100 (relative to 1980–1999, AR4 Section 10.7.1). A present-day composition commitment simulation is not part of CMIP5, so direct comparison with CMIP3 is not possible. However, the available CMIP5 results based on the RCP4.5 extension with constant RF (see Section 12.5.1) are consistent with those numbers, with an additional warming of about 0.5°C 200 years after stabilization of the forcing (Figures 12.5 and 12.42).

A measure of constant composition commitment is the fraction of realized warming which can be estimated as the ratio of the warming at a given time to the long-term equilibrium warming (e.g., Stouffer, 2004; Meehl et al., 2007b, Section 10.7.2; Eby et al., 2009; Solomon et al., 2009). EMIC simulations have been performed with RCPs forcing up to 2300 prolonged until the end of the millennium with a constant forcing set at the value reached by 2300 (Figure 12.43). When the forcing stabilizes, the fraction of realized warming is significantly below unity. However, the fraction of realized warming depends on the history of the forcing. For the RCP4.5 and RCP6.0 extension scenarios with early stabilization, it is about 75% at the time of forcing stabilization; while for RCP8.5, with stabilization occurring later, it is about 85% (see Figure 12.43); but for a 1% yr^{-1} CO_2 increase to 2 × CO_2 or 4 × CO_2 and constant forcing thereafter, the fraction of realized warming is much smaller, about 40 to 70% at the time when the forcing is kept constant. The fraction of realized warming rises typically by 10% over the century following the stabilization of forcing. Due to the long time scales in the deep ocean, full equilibrium is reached only after hundreds to thousands of years (Hansen et al., 1985; Gregory et al., 2004; Stouffer, 2004; Meehl et al., 2007b, Section 10.7.2; Knutti et al., 2008a; Danabasoglu and Gent, 2009; Held et al., 2010; Hansen et al., 2011; Li et al., 2013a).

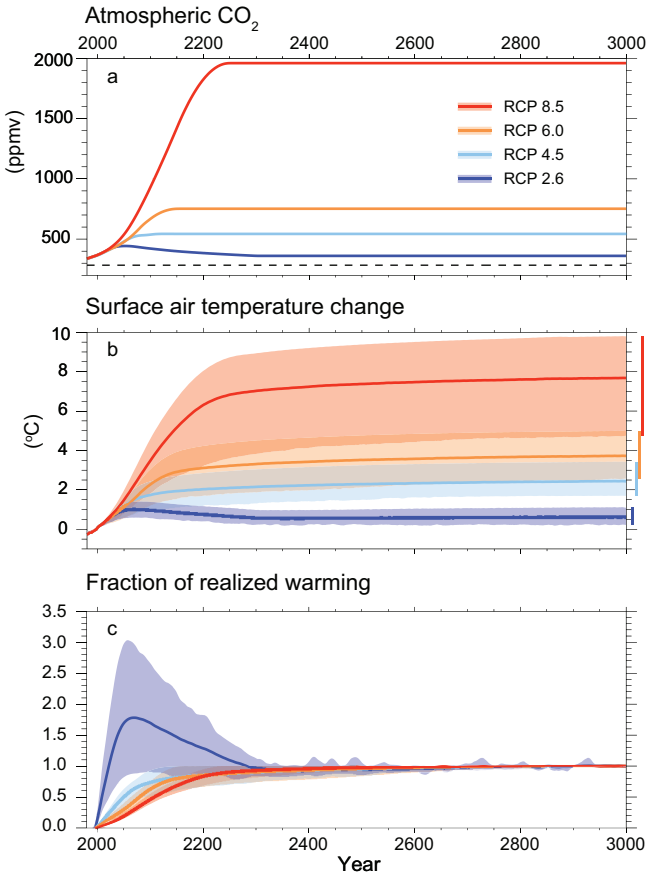

Figure 12.43 | (a) Atmospheric CO_2, (b) projected global mean surface temperature change and (c) fraction of realized warming calculated as the ratio of global temperature change at a given time to the change averaged over the 2980–2999 time period, as simulated by Earth System Models of Intermediate Complexity (EMICs) for the 4 RCPs up to 2300 followed by a constant (year 2300 level) radiative forcing up to the year 3000 (Zickfeld et al., 2013). A 10-year smoothing was applied. Shadings and bars denote the minimum to maximum range. The dashed line on (a) indicates the pre-industrial CO_2 concentration.

'Constant emission commitment' is the warming that would result from maintaining annual anthropogenic emissions at the current level. Few studies exist but it is estimated to be about 1°C to 2.5°C by 2100 assuming constant (year 2010) emissions in the future, based on the MAGICC model calibrated to CMIP3 and C^{4}MIP models (Meinshausen et al., 2011a; Meinshausen et al., 2011b) (see FAQ 12.3). Such a scenario is different from non-intervention economic scenarios, and it does not stabilize global temperature, as any plausible emission path after 2100 would cause further warming. It is also different from a constant cumulative emission scenario which implies zero emissions in the future.
